SUBTRACTION is the operation by which we take a lesser number from a greater, and find their difference. It is exactly opposite to addition, and is performed in a like manner, beginning at the greater, and reckoning downwards the units of the lesser. The greater is called the *minuend*, and the lesser the *subtrahend*.

If any figure of the subtrahend be greater than the corresponding figure of the minuend, we add ten to that of the minuend, and having found and marked the difference, we add one to the next place of the subtrahend. This is called *borrowing ten*. The reason will appear, if we consider that, when two numbers are equally increased by adding the same to both, their difference will not be altered. When we proceed as directed above, we add ten to the minuend, and we likewise add one to the higher place of the subtrahend, which is equal to ten of the lower place.

RULE.—Subtract units from units, tens from tens, and so on. If any figure of the subtrahend be greater than the corresponding one of the minuend, borrow ten.

Example.	Minuend 173694	738641
	Subtrahend 21453	379235
	Remainder 152241	359406

Subtraction.

To prove subtraction, add the subtrahend and remainder together; if their sum be equal to the minuend, the account is right.

Or subtract the remainder from the minuend. If the difference be equal to the subtrahend, the account is right.

RULE FOR COMPOUND SUBTRACTION.—Place like denominations under like; and borrow, when necessary, according to the value of the higher place.

Examples.

£	s.	d.	Cwt.	qr.	lib.	A.	R.	F.	E.
146	3	3	12	3	19	15	2	24	18
58	7	6	4	3	24	12	2	36	7
87	15	9	7	3	23	2	3	28	11

Note 1. The reason for borrowing is the same as in simple subtraction. Thus, in subtracting pence, we add 12 pence when necessary to the minuend, and at the next step we add one shilling to the subtrahend.

Note 2. When there are two places in the same denomination, if the next higher contain exactly so many tens, it is best to subtract the units first, borrowing ten when necessary; and then subtract the tens, borrowing, if there is occasion, according to the number of tens in the higher denomination.

Note 3. If the value of the higher denomination be not an even number of tens, subtract the units and tens at once, borrowing according to the value of the higher denomination.

Note 4. Some choose to subtract the place in the subtrahend, when it exceeds that of the minuend, from the value of the higher denomination, and add the minuend to the difference. This is only a different order of proceeding, and gives the same answer.

Note 5. As custom has established the method of placing the subtrahend under the minuend, we follow it when there is no reason for doing otherwise; the minuend may be placed under the subtrahend with equal propriety; and the learner should be able to work it either way with equal readiness, as this last is sometimes more convenient, of which instances will occur afterwards.

Note 6. The learner should also acquire the habit, when two numbers are marked down, of placing such a number under the lesser, that, when added together, the sum may be equal to the greater. The operation is the same as subtraction, though conceived in a different manner, and is useful in balancing accounts and on other occasions.

CHAP. IV.—MULTIPLICATION.

In multiplication two numbers are given, and it is required to find how much the first amounts to when reckoned as many times as there are units in the second. Thus, 8 multiplied by 5, or 5 times 8, is 40. The given numbers (8 and 5) are called *factors*, the first (8) the *multiplicand*, the second (5) the *multiplier*, and the amount (40) the *product*.

This operation is nothing else than addition of the same number several times repeated. If we mark 8 five times under each other, and add them, the sum is 40. But as this kind of addition is of frequent and extensive use, in order to shorten the operation, we mark down the number only once, and conceive it to be repeated as often as there are units in the multiplier.

For this purpose the learner must be thoroughly acquainted with the following multiplication table, which is composed by adding each digit twelve times.

Twice	Thrice	Four times	Five times	Six times	Seven times	Eight times	Nine times	Ten times	Eleven times	Twelve times
1 is 2	1 is 3	1 is 4	1 is 5	1 is 6	1 is 7	1 is 8	1 is 9	1 is 10	1 is 11	1 is 12
2 4	2 6	2 8	2 10	2 12	2 14	2 16	2 18	2 20	2 22	2 24
3 6	3 9	3 12	3 15	3 18	3 21	3 24	3 27	3 30	3 33	3 36
4 8	4 12	4 16	4 20	4 24	4 28	4 32	4 36	4 40	4 44	4 48
5 10	5 15	5 20	5 25	5 30	5 35	5 40	5 45	5 50	5 55	5 60
6 12	6 18	6 24	6 30	6 36	6 42	6 48	6 54	6 60	6 66	6 72
7 14	7 21	7 28	7 35	7 42	7 49	7 56	7 63	7 70	7 77	7 84
8 16	8 24	8 32	8 40	8 48	8 56	8 64	8 72	8 80	8 88	8 96
9 18	9 27	9 36	9 45	9 54	9 63	9 72	9 81	9 90	9 99	9 108
10 20	10 30	10 40	10 50	10 60	10 70	10 80	10 90	10 100	10 110	10 120
11 22	11 33	11 44	11 55	11 66	11 77	11 88	11 99	11 110	11 121	11 132
12 24	12 36	12 48	12 60	12 72	12 84	12 96	12 108	12 120	12 132	12 144

If both factors be under 12, the table exhibits the product at once. If the multiplier only be under 12, we begin at the unit place and multiply the figures in their order, carrying the tens to the higher place, as in addition.

Ex. 76859 multiplied by 4, or 76859 added 4 times.

$$\begin{array}{r} 4 \\ 76859 \\ 307436 \end{array}$$

If the multiplier be 10, we annex a cipher to the multiplicand; if the multiplier be 100, we annex two ciphers, and so on. The reason is obvious, from the use of ciphers in notation.

If the multiplier be any digit, with one or more ciphers on the right hand, we multiply by the figure, and annex an equal number of ciphers to the product. Thus, if it be required to multiply by 50, we first multiply by 5, and then annex a cipher. It is the same thing as to add the multiplicand 50 times; and this might be done by writing

the account at large, dividing the column into 10 parts of 5 lines, finding the sum of each part, and adding these ten sums together.

If the multiplier consists of several significant figures, we multiply separately by each, and add the products. It is the same as if we divided a long account of addition into parts corresponding to the figures of the multiplier.

Example. To multiply 7329 by 365.

$$\begin{array}{r} 7329 \quad 7329 \quad 7329 \\ 5 \quad 60 \quad 300 \\ 36645 \quad 439740 \quad 2198700 \\ 2675085 = 365 \text{ times.} \end{array}$$

It is obvious that 5 times the multiplicand added to 60 times, and to 300 times the same, must amount to the product required. In practice we place the products at once under each other; and as the ciphers arising from the higher places of the multiplier are lost in the addition, we omit them. Hence may be inferred the following

Multipli-
cation.

RULE.—Place the multiplier under the multiplicand, and multiply the latter successively by the significant figures of the former, placing the right-hand figure of each product under the figure of the multiplier from which it arises, then add the product.

<i>Ex.</i>	7329	42785	37846	93956
	365	91	235	8704
	36645	42785	189230	375824
	43974	385065	113538	657692
	21987	3893435	75692	751648
	2675085		8893810	817793024

A number which cannot be produced by the multiplication of two others is called a *prime number*; as 3, 5, 7, 11, and many others.

A number which may be produced by the multiplication of two or more smaller ones, is called a *composite number*; for example, 27, which arises from the multiplication of 9 by 3; and these numbers, 9 and 3, are called the *component parts* of 27.

Contractions and Varieties in Multiplication.

1st, If the multiplier be a composite number, we may multiply successively by the component parts.

<i>Ex.</i>	7638 by 45, or 5 times 9	7638
	45	9
	38190	68742
	30552	5
	343710	343710

Because the second product is equal to five times the first, and the first is equal to nine times the multiplicand, it is obvious that the second product must be five times nine, or forty-five times as great as the multiplicand.

2dly, If the multiplier be 5, which is the half of 10, we may annex a cipher and divide by 2. If it be 25, which is the fourth part of 100, we may annex two ciphers and divide by 4. Other contractions of the like kind will readily occur to the learner.

3dly, To multiply by 9, which is one less than 10, we may annex a cipher, and subtract the multiplicand from the number it composes. To multiply by 99999, or any number of 9's, annex as many ciphers, and subtract the multiplicand. The reason is obvious; and a like rule may be found though the unit place be different from 9.

4thly, Sometimes a line of the product is more easily obtained from a former line of the same than from the multiplicand.

<i>Ex. 1st.</i>	1372	2d.	1348
	84		36
	5488		8088
	10976		4044
	115248		48528

In the first example, instead of multiplying by 8, we may multiply 5488 by 2; and, in the second, instead of multiplying by 3, we may divide 8088 by 2.

5thly, Sometimes the product of two or more figures may be obtained at once, from the product of a figure already found.

<i>Ex. 1st.</i>	14356	2d.	3462321
	648		96484
	114848		13849284
	918784		166191408
	9302688		332382816
			334058579364

In the second example we multiply first by 4, then, because 12 times 4 is 48, we multiply the first line of the

product by 12, instead of multiplying separately by 8 and 4; lastly, because twice 48 is 96, we multiply the second line of the product by 2, instead of multiplying separately by 6 and 9.

When we follow this method, we must be careful to place the right-hand figure of each product under the right-hand figure of that part of the multiplier which it is derived from.

It would answer equally well in all cases to begin the work at the highest place of the multiplier; and contractions are sometimes obtained by following that order.

<i>Ex. 1st.</i>	3125	or	3125	2d.	32452
	642		642		52575
	18750		18750		162260
	12500		131250		811300
	6250		2006250		2433900
	2006250				1706163900

It is a matter of indifference which of the factors be used as the multiplier; for 4 multiplied by 3 gives the same product as 3 multiplied by 4; and the like holds universally true. To illustrate this, we may make three rows of points, four in each row, placing the . . . rows under each other; and we shall have . . . also four rows containing three points each, . . . if we reckon the rows downwards.

Multiplication is proved by repeating the operation, using the multiplier for the multiplicand, and the multiplicand for the multiplier. It may also be proven by division, or by casting out the 9's, of which afterwards; and an account, wrought by any contraction, may be proven by performing the operation at large, or by a different contraction.

COMPOUND MULTIPLICATION.

RULE I.—If the multiplier do not exceed 12, the operation is performed at once, beginning at the lowest place, and carrying according to the value of the place.

EXAMPLES.

£	s.	d.	Cwt.	qr.	lb.	A.	R.	P.	Lb.	oz.	dwt.
13	6	7	12	2	8	13	3	18	7	5	9
		9			5			6			12
119	19	3	62	3	12	83	0	28	89	5	8

RULE II.—If the multiplier be a composite number, whose component parts do not exceed 12, multiply first by one of these parts, then multiply the product by the other. Proceed in the same manner if there be more than two.

<i>Ex. 1st.</i>	£15	3	8 by 32 = 8 × 4
			8
	£121	9	4 = 8 times.
			4
	£485	17	4 = 32 times.
2d.	£17	3	8 by 75 = 5 × 5 × 3
			3
	£51	11	— = 3 times.
			5
	£257	15	— = 15 times.
			5
	£1288	15	— = 75 times.

Note 1. Although the component parts will answer in any order, it is best, when it can be done, to take them in such order as may clear off some of the lower places at the first multiplication, as is done in *Ex. 2d.*

Note 2. The operation may be proved by taking the

If the divisor be contained oftener than ten times in the dividend, the operation requires as many steps as

Division. there are figures in the quotient. For instance, if the quotient be greater than 100, but less than 1000, it requires 3 steps. We first inquire how many hundred times the divisor is contained in the dividend, and subtract the amount of these hundreds. Then we inquire how often it is contained ten times in the remainder, and subtract the amount of these tens. Lastly, we inquire how many single times it is contained in the remainder. The method of proceeding will appear from the following example:

$$\begin{array}{r}
 \text{From } 5936 \\
 \text{Take } 5600 = 700 \text{ times } 8. \\
 \text{Rem. } 336 \\
 \text{From which take } 320 = 40 \text{ times } 8. \\
 \text{Rem. } 16 \\
 \text{From which take } 16 = 2 \text{ times } 8. \\
 0 \quad 742 \text{ times } 8 \text{ in all.}
 \end{array}$$

It is obvious, that as often as 8 is contained in 59, so many hundred times it will be contained in 5900, or in 5936; and as often as it is contained in 33, so many ten times it will be contained in 330, or in 336; and thus the higher places of the quotient will be obtained with equal ease as the lower. The operation might be performed by subtracting 8 continually from the dividend, which will lead to the same conclusion by a very tedious process. After 700 subtractions, the remainder would be 336; after 40 more it would be 16; and after 2 more the dividend would be entirely exhausted. In practice we omit the ciphers, and proceed by the following

RULES.—1. Assume as many figures on the left hand of the multiplier as contain the divisor once or oftener; find how many times they contain it, and place the answer as the highest figure of the quotient.

2. Multiply the divisor by the figure you have found, and place the product under the part of the dividend from which it is obtained.

3. Subtract the product from the figures above it.

4. Bring down the next figure of the dividend to the remainder, and divide the number it makes up as before.

Examples.] 1st, 8)5936(742 2d, 63)30114(478

$$\begin{array}{r}
 56 \dots \\
 33 \\
 32 \\
 16 \\
 16 \\
 \hline
 3d, 365)974932(2671\frac{17}{365} \\
 730 \dots \\
 2449 \\
 2190 \\
 \hline
 2593 \\
 2555 \\
 \hline
 382 \\
 365 \\
 \hline
 \text{Remainder } 17
 \end{array}$$

The numbers which we divide, as 59, 33, and 16, in the first example, are called *dividuals*.

It is usual to mark a point under the figures of the dividend as they are brought down, to prevent mistakes.

If there be a remainder, the division is completed by a vulgar fraction, whose numerator is the remainder, and its denominator the divisor. Thus, in Ex. 3 the quotient is 2671, and the remainder 17; and the quotient completed is $2671\frac{17}{365}$.

A number which divides another without a remainder is said to measure it; and the several numbers which measure

another are called its *aliquot parts*. Thus 2, 4, 6, 8, and 12, are aliquot parts of 24. As it is often useful to discover numbers which measure others, we may observe,

1st, Every number ending with an even figure, that is, with 2, 4, 6, 8, or 0, is measured by 2.

2dly, Every number ending with 5 or 0 is measured by 5.

3dly, Every number whose figures, when added, amount to an even number of 3's or 9's, is measured by 3 or 9, respectively.

Contractions and Varieties in Division.

1st, When the divisor does not exceed 12, the whole computation may be performed without setting down any figures except the quotient.

$$\begin{array}{r}
 \text{Ex. } 7)35868(5124 \quad \text{or } 7)35868 \\
 5124
 \end{array}$$

2dly, When the divisor is a composite number, and one of the component parts also measures the dividend, we may divide successively by the component parts.

$$\begin{array}{r}
 \text{Ex. 1st, } 30114 \text{ by } 63 \quad 2d, 975 \text{ by } 105 = 5 \times 7 \times 3 \\
 9)30114 \quad 5)975 \\
 7)3346 \quad 3)195 \\
 \text{Quotient } 478 \quad \text{Quotient } 9\frac{2}{7}
 \end{array}$$

This method might be also used although the component parts of the divisor do not measure the dividend; but the management of the remainder requires the doctrine of vulgar fractions.

3dly, When there are ciphers annexed to the divisor, cut them off, and cut off an equal number of figures from the dividend; annex those figures to the remainder.

$$\begin{array}{r}
 \text{Ex. To divide } 378643 \text{ by } 5200. \\
 52)00378643(72\frac{1243}{200} \\
 364 \dots \\
 146 \\
 104 \\
 \hline
 4243
 \end{array}$$

The reason will appear by performing the operation at large, and comparing the steps.

To divide by 10, 100, 1000, or the like: Cut off as many figures on the right hand of the dividend as there are ciphers in the divisor. The figures which remain on the left hand compose the quotient, and the figures cut off compose the remainder.

Note.—Since 4 times 25 make 100, instead of dividing by 25, we may multiply the dividend by 4, and cut off the two last figures from the product. The figures left will be the quotient, and those cut off the remainder. In like manner, to divide by 125, which multiplied by 8 produces 1000, we may multiply the dividend by 8, and cut off three figures, which will be the remainder, and those left the quotient.

4thly, When the divisor consists of several figures, we may try them separately, by inquiring how often the first figure of the divisor is contained in the first figure of the dividend, and then considering whether the second and following figures of the divisor be contained as often in the corresponding ones of the dividend with the remainder (if any) prefixed. If not, we must begin again, and make trial of a lower number. When the remainder is nine or upwards, we may be sure the division will hold through the lower places; and it is unnecessary to continue the trial farther.

5thly, We may make a table of the products of the divisor, multiplied by the nine digits, in order to discover more readily how often it is contained in each dividual. This is convenient when the dividend is very long, or when it is required to divide frequently by the same divisor

Div-on.

78 by 2 = 146

6thly, To divide by 9, 99, 999, or any number of 9's, transcribe under the dividend part of the same, shifting the highest figure as many places to the right hand as there are 9's in the divisor. Transcribe it again, with the like change of place, as often as the length of the dividend admits; add these together, and cut off as many figures from the right hand of the sum as there are 9's in the divisor. The figures which remain on the left hand compose the quotient, and those cut off the remainder.

If there be any carriage to the unit place of the quotient, add the number carried likewise to the remainder, as in Ex. 2; and if the figures cut off be all 9's, add 1 to the quotient, and there is no remainder.

476|999
1
Quotient 477

To explain the reason of this, we must recollect, that whatever number of hundreds any dividend contains, it contains an equal number of 99's, together with an equal number of units. In Ex. 1, the dividend contains 3241 hundreds, and a remainder of 23. It therefore contains 3241 times 99, and also 3241, besides the remainder already mentioned.—Again, 3241 contains 32 hundreds and a remainder of 41. It therefore contains 32 99's, and also 32, besides the remainder of 41. Consequently the dividend contains 99, altogether, 3241 times and 32 times, that is, 3273 times, and the remainder consists of 23, 41, and 32, added, which make 96.

As multiplication supplies the place of frequent additions, and division of frequent subtractions, they are only repetitions and contractions of the simple rules; and, when compared together, their tendency is exactly opposite. As numbers, increased by addition, are diminished and brought back to their original quantity by subtraction; in like manner numbers compounded by multiplication are reduced by division to the parts from which they were compounded. The multiplier shows how many additions are necessary to produce the number; and the quotient shows how many subtractions are necessary to exhaust it. It follows that the product, divided by the multiplicand, will quote the multiplier; and because either factor may be assumed for the multiplicand, therefore the product divided by either factor quotes the other. It follows, also, that the dividend is equal to the product of the

divisor and quotient multiplied together; and hence these operations mutually prove each other.

To prove multiplication: Divide the product by either factor. If the operation be right, the quotient is the other factor, and there is no remainder.

To prove division: Multiply the divisor and quotient together; to the product add the remainder, if any; and, if the operation be right, it makes up the dividend. Otherwise divide the dividend (after subtracting the remainder, if any) by the quotient. If the operation be right, it will quote the divisor. The reason of all those rules may be collected from the last paragraph.

COMPOUND DIVISION.

RULE I.—When the dividend only consists of different denominations, divide the higher denomination, and reduce the remainder to the next lower, taking in (p. 547, Reduction) the given number of that denomination, and continue the division.

Examples.

Divide £465. 12s. 8d.
by 72.

£	s.	d.	£	s.	d.
72)	465	12 8	(6	9	4
	432	...			
	33				
	20				
72)	672				
	648				
	24				
	12				
72)	296				
	288				
	8	Rem.			

Divide 345 cwt. 1 qr. 8 lb.
by 22.

	28			28	
	120			3100	
	28			770	
	4 00		)	108 00(27 quot.	

It is best not to reduce the terms lower than is necessary to render them equal. For instance, if each of them consists of an even number of sixpences, fourpences, or the like, we reduce them to sixpences or fourpences, but not to pence.

The use of division is to find either of the factors by whose multiplication a given number is produced when the other factor is given, and therefore is of two kinds, since either the multiplier or the multiplicand may be

Division. given. If the former be given, it discovers what that number is which is contained so many times in another. If the latter be given, it discovers how many times one number is contained in another. Thus, it answers the questions of an opposite kind to those mentioned under Rule IV. p. 547, as, to find the quantity of a single parcel or share; to find the value, weight, or measure, of a single article; to find how much work is done, provisions consumed, interest incurred, or the like, in a single day, &c.

The last use of division is a kind of reduction exactly opposite to that described under Rule V. p. 547. The manner of conducting and arranging it, when there are several denominations in the question, will appear from the following examples.

1 To reduce 15783 pence to pounds, shillings, and pence.

$$\begin{array}{r}
 12 \overline{) 15783} \quad 1315(65 \\
 \underline{12000} \quad 120 \cdot \\
 37 \quad 115 \\
 \underline{36} \quad 100 \\
 18 \quad 15 \\
 \underline{12} \\
 63 \\
 \underline{60} \\
 3
 \end{array}$$

Answer, £65. 15s. 3d.

2. To reduce 174865 grs. to lbs. oz. and dwt. Troy.

$$\begin{array}{r}
 20 \quad 12 \\
 24 \overline{) 174865} \quad 7286(364(30 \\
 \underline{168000} \quad 60 \cdot \quad 36 \cdot \\
 68 \quad 128 \quad 04 \\
 \underline{48} \quad 120 \\
 206 \quad 86 \\
 \underline{192} \quad 80 \\
 145 \quad 6 \\
 \underline{144} \\
 1
 \end{array}$$

Ans. 30 lb. 4 oz. 6 dwt. 1 gr.

In the first example we reduce 15783 pence to shillings, by dividing by 12, and obtain 1315 shillings, and a remainder of 3 pence. Then we reduce 1315 shillings to pounds by dividing by 20, and obtain 65 pounds and a remainder of 15 shillings. The divisions might have been contracted.

In the practice of arithmetic questions often occur which require both multiplication and division to resolve. This happens in reduction, when the higher denomination does not contain an exact number of the lower.

RULE FOR MIXED REDUCTION.—Reduce the given denomination by multiplication to some lower one which is an aliquot part of both; then reduce that by division to the denomination required.

Ex.—Reduce £31742 to guineas.

$$\begin{array}{r}
 31742 \\
 20 \\
 21 \overline{) 634840} \quad 30230 \\
 \underline{630000} \\
 048 \\
 \underline{42} \\
 64 \\
 \underline{63} \\
 10
 \end{array}$$

10 Answer, 30230 guineas and 10 shillings.

Here we multiply by 20, which reduces the pounds to shillings, and divide the product by 21, which reduces the shillings to guineas.

Note 1. Guineas may be reduced to pounds by adding one twentieth part of the number.

2. Pounds may be reduced to merks by adding one half.

3. Merks may be reduced to pounds by subtracting one third.

Another case which requires both multiplication and division is, when the value, weight, measure, or duration of any quantity is given, and the value, &c. of a different quantity required, we first find the value, &c. of a single article by division, and then the value, &c. of the quantity required, by multiplication.

Ex. If 3 yards cost 15s. 9d. what will 7 yards cost at the same rate?

$$\begin{array}{r}
 s. \quad d. \\
 3) \quad 15 \quad 9 \text{ price of 3 yards.} \\
 \quad \quad 5 \quad 3 \text{ price of 1 yard, by Rule IV. p. 547.} \\
 \quad \quad \quad 7
 \end{array}$$

£1 16 9 price of 7 yards (by par. ult. p. 549, col. 2.)

Many other instances might be adduced where the operation and the reasons of it are equally obvious. These are generally, though unnecessarily, referred to the rule of proportion.

We shall now offer a general observation on all the operations in arithmetic. When a computation requires several steps, we obtain a just answer, whatever order we follow. Some arrangements may be preferable to others in point of ease, but all of them lead to the same conclusion. In addition or subtraction we may take the articles in any order, as is evident from the idea of number; or we may collect them into several sums, and add or subtract these either separately or together. When both the simple operations are required to be repeated, we may either complete one of them first, or may introduce them promiscuously; and the compound operations admit of the same variety. When several numbers are to be multiplied together, we may take the factors in any order, or we may arrange them into several classes, find the product of each class, and then multiply the products together. When a number is to be divided by several others we may take the divisors in any order, or we may multiply them into each other, and divide by the product; or we may multiply them into several parcels, and divide by the products successively. Lastly, When multiplication and division are both required, we may begin with either; and when both are repeatedly necessary, we may collect the multipliers into one product and the divisors into another, or we may collect them into parcels, or use them singly, and that in any order. Still we shall obtain the proper answer if none of the terms be neglected.

When both multiplication and division are necessary to obtain the answer of a question, it is generally best to begin with the multiplication, as this order keeps the account as clear as possible from fractions. The example last given may be wrought accordingly as follows:

$$\begin{array}{r}
 s. \quad d. \\
 15 \quad 9 \\
 \underline{7} \\
 3) 5 \quad 10 \quad 3 \\
 \underline{1 \quad 16 \quad 9}
 \end{array}$$

Some accountants prove the operations of arithmetic by a method which they call casting out the 9's, depending on the following principles:

1st, If several numbers be divided by any divisor (the remainders being always added to the next number), the sum of the quotients, and the last remainder, will be the same as those obtained when the sum of the number is divided by the same divisor. Thus, 19, 15, and 23, contain together as many 5's, as many 7's, &c. as their sum 57 does, and the remainders are the same; and, in this way, addition may be proven by division. It is from the correspondence of the remainders that the proof by casting out the 9's is deduced.

2dly, If any figure with ciphers annexed be divided by 9, the quotient consists entirely of that figure; and the remainder is also the same. Thus, 40 divided by 9 quotes 4, remainder 4; and 400 divided by 9 quotes 44, remainder 4. The same holds with all the digits, and the reason will be easily understood: every digit, with a ci-

Divisor. pher annexed, contains exactly so many tens; it must therefore contain an equal number of 9's, besides a remainder of an equal number of units.

3dly, If any number be divided by 9, the remainder is equal to the sum of the figures of the number, or to the remainder obtained, when that sum is divided by 9. For instance, 3765 divided by 9 leaves a remainder of 3; and the sum of 3, 7, 6, and 5, is 21, which divided by 9 leaves a remainder of 3. The reason of this will appear from the following illustration:

3000 divided by 9 quotes 333, remainder 3	
700	9 quotes 77, remainder 7
60	9 quotes 6, remainder 6
5	9 quotes 0, remainder 5
3765	416, sum of rem. 21

Again: 21 divided by 9 quotes 2, remainder 3;

wherefore, 3765 divided by 9 quotes 418, remainder 3; for the reason given. Hence we may collect the following rules for practice:

To cast the 9's out of any number, or to find what remainder will be left when any number is divided by 9: add the figures; and when the sum exceeds 9, add the figures which would express it. Pass by the 9's; and when the sum comes exactly to 9, neglect it, and begin anew. For example, if it be required to cast the 9's out of 3573294, we reckon thus; 3 and 5 are 8, and 7 is 15; 1 and 5 are 6, and 3 is 9, which we neglect; 2 and (passing by 9) 4 are 6; which is the remainder or **RESULT**. If the article out of which the 9's are to be cast contains more denominations than one, we cast the 9's out of the higher, and multiply the result by the value of the lower, and carry on the product (casting out the 9's, if necessary) to the lower.

To prove addition, cast the 9's out of the several articles, carrying the results to the following articles; cast them also out of the sum. If the operation be right, the results will agree.

To prove subtraction, cast the 9's out of the minuend; cast them also out of the subtrahend and remainder together; and if you obtain the same result, the operation is presumed right.

To prove multiplication, cast the 9's out of the multiplicand, and also out of the multiplier if above 9. Multiply the results together, and cast the 9's, if necessary, out of their product. Then cast the 9's out of the product, and observe if this result correspond with the former.

Ex. 1st, 9276 res. 6 $\times$ 8 = 48 res. 3.

8

74208 res. 3.

2d, 7898 res. 5 $\times$ 3 = 15 res. 6.

48 res. 3

63184

31592

379104 res. 6.

The reason of this will be evident, if we consider multiplication under the view of repeated addition. In the first example it is obviously the same. In the second, we may suppose the multiplicand repeated 48 times. If this be done, and the 9's cast out, the result, at the end of the 9th line, will be 0; for any number, repeated 9 times, and divided by 9, leaves no remainder. The same must happen at the end of the 18th, 27th, 36th, and 45th lines; and the last result will be the same as if the multiplicand had only been repeated 3 times. This is the reason for casting out the 9's from the multiplier as well as the multiplicand.

To prove division, cast the 9's out of the divisor, and

also out of the quotient; multiply the results, and cast the 9's out of the product. If there be any remainder, add to it the result, casting out the 9's if necessary. If the account be right, the last result will agree with that obtained from the dividend.

Ex. 42) 2490 (59 res. 5 $\times$ 6 = 30 res. 3.

res. 6. 210

390

378

Rem. 12 - - - res. 3.

6

And the result of the dividend is 6.

This depends on the same reason as the last; for the dividend is equal to the product of the divisor, and quotient added to the remainder.

We cannot recommend this method, as it lies under the following disadvantages.

1st, If an error of 9, or any of its multiples, be committed, the results will nevertheless agree; and so the error will remain undiscovered. And this will always be the case when a figure is placed or reckoned in a wrong column, which is one of the most frequent causes of error.

2dly, When it appears by the disagreement of the results that an error has been committed, the particular figure or figures in which the error lies are not pointed out, and consequently it is not easily corrected.

CHAP. VI.—RULE OF PROPORTION.

SECT. I.—SIMPLE PROPORTION.

Quantities are reckoned proportional to each other when they are connected in such a manner, that if one of them be increased or diminished, the other increases or diminishes at the same time, and the degree of the alteration on each is a like part of its original measure. Thus, four numbers are in the same proportion, the first to the second as the third to the fourth, when the first contains the second, or any part of it, as often as the third contains the fourth, or the like part of it. In either of these cases, the quotient of the first divided by the second is equal to that of the third divided by the fourth; and this quotient may be called the *measure of the proportion*.

Proportionals are marked down in the following manner:

6 : 3 :: 8 : 4

12 : 36 :: 9 : 27

9 : 6 :: 24 : 16

16 : 24 :: 10 : 15

The rule of Proportion directs us, when three numbers are given, how to find a fourth, to which the third may have the same proportion that the first has to the second. It is sometimes called the *Rule of Three*, from the three numbers given; and sometimes the *Golden Rule*, from its various and extensive utility.

RULE. *Multiply the second and third terms together, and divide the product by the first.*

Ex. To find a fourth proportional to 18, 27, and 34.

18 : 27 :: 34 : 51

34

108

81

18)918(51

90

18

18

To explain the reason of this, we must observe, that if

Simple
Proportion.

two or more numbers be multiplied or divided alike, the products or quotients will have the same proportion.

$$18 : 27$$

$$\text{Multiplied by } 34, 612 : 918$$

$$\text{Divided by } 18, 34 : 51$$

The products 612, 918, and the quotients 34, 51, have therefore the same proportion to each other that 18 has to 27. In the course of this operation, the products of the first and third terms are divided by the first; therefore the quotient is equal to the third.

The first and second terms must always be of the same kind; that is, either both moneys, weights, measures, both abstract numbers, or the like. The fourth, or number sought, is of the same kind as the third.

When any of the terms is in more denominations than one, we may reduce them all to the lowest. But this is not always necessary. The first and second should not be reduced lower than directed, p. 549, col. 2, par. penult.; and when either the second or third is a simple number, the other, though in different denominations, may be multiplied without reduction.

$$\begin{array}{r} \text{Ex. } 5 : 7 :: 25 \text{ } \begin{array}{l} \text{£} \text{ } s. \text{ } d. \\ 11 \text{ } 3 \end{array} \\ \hline 7 \\ \hline 5) 178 \text{ } 18 \text{ } 9 \end{array} \quad \begin{array}{l} \text{£} \text{ } s. \text{ } d. \\ 35 \text{ } 15 \text{ } 9 \end{array}$$

The accountant must consider the nature of every question, and observe the circumstance which the proportion depends on; and common sense will direct him to this if the terms of the question be understood. It is evident that the value, weight, and measure of any commodity is proportioned to its quantity; that the amount of work or consumption is proportioned to the time; that gain, loss, or interest, when the rate and time are fixed, is proportioned to the capital sum from which it arises; and that the effect produced by any cause is proportioned to the extent of the cause. In these and many other cases the proportion is direct, and the number sought increases or diminishes along with the term from which it is derived.

In some questions, the number sought becomes less when the circumstances from which it is derived become greater. Thus, when the price of goods increases, the quantity which may be bought for a given sum is smaller; when the number of men employed at work is increased, the time in which they may complete it becomes shorter; and when the activity of any cause is increased, the quantity necessary to produce a given effect is diminished. In these and the like the proportion is said to be inverse.

GENERAL RULE for stating all questions, whether direct or inverse. *Place that number for the third term which signifies the same kind of thing with what is sought, and consider whether the number sought will be greater or less. If greater, place the least of the other terms for the first; but if less, place the greatest for the first.*

Ex. 1st, If 30 horses plough 12 acres, how many will 42 plough in the same time?

$$\begin{array}{l} H. \quad H. \quad A \\ 30 :: 42 :: 12 : \text{answer.} \end{array}$$

Here, because the thing sought is a number of acres, the place 12, the given number of acres, for the third term; and because 42 horses will plough more than 30, we make the lesser number, 30, the first term, and the greater number, 42, the second term.

Ex. 2d, If 40 horses be maintained for a certain sum on hay, at 5d. per stone, how many will be maintained on the same sum when the price of hay rises to 8d.

$$\begin{array}{l} d. \quad d. \quad H. \\ 8 : 5 :: 40 : \text{answer.} \end{array}$$

Here, because a number of horses is sought, we make the given number of horses, 40, the third term; and because fewer will be maintained for the same money when the price of hay is dearer, we make the greater price, 8d. the first term, and the lesser price, 5d. the second term.

The first of these examples is direct, the second inverse. Every question consists of a supposition and demand. In the first, the supposition is, that 30 horses plough 12 acres, and the demand, *how many 42 will plough*; and the first term of the proportion, 30, is found in the supposition, in this and every other direct question. In the second, the supposition is, that 40 horses are maintained on hay at 5d., and the demand, *how many will be maintained on hay at 8d.*? and the first term of the proportion, 8, is found in the demand, in this and every other inverse question.

When a proportion is stated, if the first and second terms, or first and third, be measured by the same number, we may divide them by that measure, and use the quotients in their stead.

Ex. If 36 yards cost 42 shillings, what will 27 cost?

$$\begin{array}{r} Y. \quad Y. \quad sh. \\ 36 : 27 :: 42 \\ 4 : 3 :: 42 \\ \hline 3 \\ \hline 4) 126(31 \text{ } 6, \text{ the answer.} \end{array} \quad \begin{array}{l} \text{Here } 36 \text{ and } 27 \text{ are both} \\ \text{measured by } 9, \text{ and we work} \\ \text{with the quotients } 4 \text{ and } 3. \end{array}$$

SECT. II.—COMPOUND PROPORTION.

Sometimes the proportion depends upon several circumstances. Thus, it may be asked, if 18 men consume 6 bolls of corn in 28 days, how much will 24 men consume in 56 days? Here the quantity required depends partly on the number of men, partly on the time; and the question may be resolved into the two following ones:

1st, If 18 men consume 6 bolls in a certain time, how many will 24 men consume in the same time?

$$\begin{array}{r} M. \quad M. \quad B. \quad B. \\ 18 : 24 :: 6 : 8 \\ \hline 6 \end{array} \quad \begin{array}{l} \text{Answer, } 24 \text{ men will consume } 8 \\ \text{bolls in the same time.} \end{array}$$

$$18) 144(8$$

2d, If a certain number of men consume 8 bolls in 28 days, how many will they consume in 56 days?

$$\begin{array}{r} D. \quad D. \quad B. \quad B. \\ 28 : 56 :: 8 : 16 \\ \hline 8 \end{array} \quad \begin{array}{l} \text{Ans. The same number of men} \\ \text{will consume } 16 \text{ bolls in } 56 \text{ days.} \end{array}$$

$$28) 448(16$$

In the course of this operation, the original number of bolls, 6, is first multiplied into 24, then divided by 18, then multiplied into 56, then divided by 28. It would answer the same purpose to collect the multipliers into one product and the divisors into another, and then to multiply the given number of bolls by the former, and divide the product by the latter, p. 550, col. 2.

The above question may therefore be stated and wrought as follows:

$$\begin{array}{r} \text{Men } 18 : 24 :: 6 \text{ bolls} \\ \text{Days } 28 : 56 \\ \hline 144 \quad 144 \\ 36 \quad 120 \\ \hline 504 \quad 1344 \\ \hline 6 \end{array} \quad \begin{array}{l} \text{Here we multiply } 18 \text{ into} \\ 28 \text{ for a divisor, and } 6 \text{ into} \\ \text{the product of } 24 \text{ by } 56 \text{ for} \\ \text{a dividend.} \end{array}$$

$$504) 8064(16, \text{ answer.}$$

In general, state the several particulars on which the question depends, as so many simple proportions, attending to the sense of the question to discover whether the proportions should be stated directly or inversely; then multiply all the terms in the first rank together, and all

those in the second rank together, and work with the product as directed in the simple rule (Sect. i. p. 551.)

Ex. If 100 men make 3 miles of road in 27 days, in how many days will 150 men make 5 miles?
Men 150 : 100 :: 27 days.

$$\begin{array}{r} 3 \quad 5 \\ 450 \quad 500 \\ \hline 27 \end{array}$$

450)13500(30 days, *ans.*

Here the first stating is inverse, because more men will do it in fewer days; but the second is direct, because more miles will require more days.

The following contraction is often useful. After stating the proportion, if the same number occurs in both ranks, dash it out from both; or, if any term in the first rank and another in the second rank are measured by the same numbers, dash out the original terms, and use the quotients in their stead.

Ex. If 18 men consume £30 value of corn in 9 months when the price is 16s. per boll, how many will consume £54 value in 6 months when the price is 12s. per boll? In this question the proportion depends upon three particulars—the value of corn, the time, and price; the first of which is direct, because the greater the value of provisions is, the more time is required to consume them; but the second and third are inverse, for the greater the time and price are, fewer men will consume an equal value.

Value 30 : 54 :: 18 men.
Months 9 : 6
Price 12 : 16

Here we observe 6 in the first rank measures 54 in the second; so we dash them out, and place the quotient 9 in the second rank. Next, because 30 and 9 are both measured by 3, we dash them out, and place down the quotients 10 and 3; then, because 12 and 16 are both measured by 4, we dash them out and place down the quotients 3 and 4. Lastly, because there is now 3 in both columns, we dash them out, and work with the remaining terms, according to the rule.

The moneys, weights, and measures of different countries may be reduced from the proportion which they bear to each other.

Ex. If 112 lb. avoirdupois make 104 lb. of Holland, and 100 lb. of Holland make 89 of Geneva, and 110 of Geneva make 117 of Seville, how many lbs. of Seville will make 100 lb. avoirdupois?

$$\begin{array}{l} 112 : 104 :: 100 \\ 100 : 89 \\ 110 : 117 \end{array}$$

If it be required how many lb. avoirdupois will make 100 of Seville, then the terms must be placed in the different columns thus,—

$$\begin{array}{l} 104 : 112 :: 100 \\ 89 : 100 \\ 117 : 110 \end{array}$$

SECT. III.—DISTRIBUTIVE PROPORTION.

If it be required to divide a number into parts which have the same proportion to each other that several other given numbers have, we add these numbers together, and state the following proportion: As the sum is to the particular numbers, so is the number required to be divided to the several parts sought.

Ex. 1. Four partners engage to trade in company; A's stock is £150, B's £320, C's £350, D's £500, and they gain £730: Required how much belongs to each if the gain be divided among them in proportion to their stocks?

VOL. III.

A's stock	£150	1320 : 150 :: 730 :	£ 82	19	1—120
B's	320	1320 : 320 :: 730 :	176	19	4—960
C's	350	1320 : 350 :: 730 :	193	11	2—720
D's	500	1320 : 500 :: 730 :	276	10	3—840

Whole stock £1320

Proof £730

This account is proved by adding the gains of the partners, the sum of which will be equal to the whole gain if the operation be right; but if there be remainders, they must be added, their sum divided by the common divisor, and the quotient carried to the lowest place.

Ex. 2. A bankrupt owes A £146, B £170, C £45, D £480, and E £72; his whole effects are only £342. 7s. 6d. How much should each have?

A's debt	£146	913 : 146 :: £342 7 6 :	£ 54	15	A's share.
B's	170	913 : 170 :: 342 7 6 :	63	15	B's
C's	45	913 : 45 :: 342 7 6 :	16	17 6	C's
D's	480	913 : 480 :: 342 7 6 :	180		D's
E's	72	913 : 72 :: 342 7 6 :	27		E's

£913

£342 7 6

This might also be calculated by finding what composition the bankrupt was able to pay per pound, which is obtained by dividing the amount of his effects by the amount of his debts, and comes to 7s. 6d., and then finding by the rules of practice how much each debt came to at that rate.

CHAP. VII.—RULES FOR PRACTICE.

The operations explained in the foregoing chapters comprehend the whole system of arithmetic, and are sufficient for every computation. In many cases, however, the work may be contracted by adverting to the particular circumstances of the question. We shall explain in this chapter the most useful methods which practice has suggested for rendering mercantile computations easy, in which the four elementary rules of arithmetic are sometimes jointly, sometimes separately employed.

SECT. I.—COMPUTATION OF PRICES.

The value of any number of articles, at a pound, a shilling, or a penny, is an equal number of pounds, shillings, or pence; and these two last are easily reduced to pounds. The value at any other rate may be calculated by easy methods, depending on some contraction already explained, or on one or more of the following principles.

1st, If the rate be an aliquot part of a pound, a shilling, or a penny, then an exact number of articles may be bought for a pound, a shilling, or a penny; and the value is found by dividing the given number accordingly. Thus, to find the price of so many yards at 2s. 6d., which is the eighth part of a pound, we divide the quantity by eight, because every eight yards cost £1.

2d, If the rate be equal to the sum of two other rates which are easily calculated, the value may be found by computing these separately, and adding the sums obtained. Thus, the price of so many yards at 9d. is found by adding their prices at 6d. and 3d. together.

3d, If the rate be equal to the difference of two easy rates, they may be calculated separately, and the lesser subtracted from the greater. Thus, the value of so many articles at 11d. is found by subtracting their value at a penny from their value at a shilling. We may suppose that a shilling was paid for each article, and then a penny returned on each.

4th, If the rate be a composite number, the value may be found by calculating what it comes to at one of the component parts, and multiplying the same by the other.

CASE I. When the rate is an aliquot part of a pound, divide the quantity by the number which may be bought for a pound.

4 A

Practice.

Table of the aliquot parts of £1.

10 shillings = $\frac{1}{2}$ of £1.	1s. 4d. = $\frac{1}{13}$ of £1.
6s. 8d. = $\frac{1}{3}$	1s. 3d. = $\frac{1}{16}$
5s. = $\frac{1}{4}$	1s. = $\frac{1}{20}$
4s. = $\frac{1}{5}$	8d. = $\frac{1}{30}$
3s. 4d. = $\frac{1}{6}$	6d. = $\frac{1}{40}$
2s. 6d. = $\frac{1}{8}$	4d. = $\frac{1}{60}$
2s. = $\frac{1}{10}$	3d. = $\frac{1}{80}$
1s. 8d. = $\frac{1}{12}$	2d. = $\frac{1}{100}$

Ex. 1st.] What is the value of 7463 yards, at 4s.?

5)7463
£1492. 12s.

2d.] What is the value of 1773 yards, at 3d.?

80)1773
£22. 3s. 3d.

In the first example we divide by 5 because 4s. is $\frac{1}{5}$ of a pound; the quotient 1492 shows how many pounds they amount to; besides which there remain three yards at 4s., and these come to 12s. In the second example we divide by 80, as directed, and the quotient gives £22, and the remainder 13 yards, which at 3d. come to 3s. 3d.

This method can only be used in calculating for the particular prices specified in the table. The following six cases comprehend all possible rates, and will therefore exhibit different methods of solving the foregoing questions.

CASE II. When the rate consists of shillings only, multiply the quantity by the number of shillings, and divide the product by 20: Or, if the number of shillings be even, multiply by half the number, and divide the product by 10.

Ex. 1st.] 4573 at 13s.

13
13719
4573
20)59449
£2972. 9s.

2d.] 7543 at 14s.

7
10)52801
£5280. 2s.

It is easy to perceive that the method in which the second example is wrought must give the same answer as if the quantity had been multiplied by 14 and divided by 20; and as the division by 10 doubles the last figure for shillings, and continues all the rest unchanged for pounds, we may obtain the answer at once, by doubling the right-hand figure of the product before we set it down.

If the rate be the sum of two or more aliquot parts of a pound, we may calculate these as directed in Case I. and add them. If it be any odd number of shillings, we may calculate for the even number next lower, and add thereto the value of a shilling. If it be 19s. we may subtract the value at a shilling from the value at a pound.

CASE III. When the rate consists of pence only.

Method 1. If the rate be an aliquot part of a shilling, divide the quantity accordingly, which gives the answer in shillings; if not, it may be divided into two or more aliquot parts: calculate these separately, and add the values; reduce the answer to pounds.

1 penny is $\frac{1}{12}$ of a shilling.

2d. $\frac{1}{6}$ of ditto.

3d. $\frac{1}{4}$ of ditto.

4d. $\frac{1}{3}$ of ditto.

6d. $\frac{1}{2}$ of ditto.

5d. is the sum of 4d. and 1d. or of 2d. and 3d.

7d. is the sum of 4d. and 3d. or of 6d. and 1d.

8d. is the sum of 6d. and 2d. or the double of 4d.

9d. is the sum of 6d. and 3d.

10d. is the sum of 6d. and 4d.

11d. is the sum of 6d. 3d. and 2d.

Ex. 1st.] 7423 at 4d.

3)7423
20)2474 4
£123 14 4

Here, because 4d. is one third of a shilling, we divide by 3, which gives the price in shillings, and reduce these by division to pounds.

Ex. 2d.]

At 6d. = $\frac{1}{2}$ of 1s. 4893
At 3d. = $\frac{1}{4}$ of 6d. 2446 6
At 9d. 7339 6

Ex. 3d.]

At 6d. = $\frac{1}{2}$ of 1s. 2428
At 3d. = $\frac{1}{4}$ of 6d. 1214
At 2d. = $\frac{1}{2}$ of 6d. 809 4
11d. 4451 4
£222 11 4

It is sometimes easier to calculate at two rates whose difference is the rate required, and subtract the lesser value from the greater. Thus, the last example may be wrought by subtracting the value at a penny from the value at a shilling. The remainder must be the value at 11d.
At 1s. 4856s.
At 1d. = $\frac{1}{20}$ 404 8
At 11d. 4451 4
£222 11 4

Method 2. Multiply the quantity by the number of pence, the product is the answer in pence. Reduce it to pounds.

Method 3. Find the value at a penny by division, and multiply the same by the number of pence.

CASE IV. When the rate consists of farthings only, find the value in pence, and reduce it by division to pounds.

Ex. 1st.] 37843 at 1 farthing.

4)37843 farth.
12) 9460 $\frac{3}{4}$ pence
788 $\frac{4}{4}$
£39 8 $\frac{4}{4}$
3d, 72564 at $\frac{3}{4}$
3
4)217692 farth.
12) 54423 pence
4535 3
£226 15 3

2d.] 23754 at $\frac{1}{4}$ d.
2) 23754 halfpence
12) 11877 pence
989 9
£49 9 9

Or, 72564

At $\frac{1}{2}$ d. 36282 d.
At $\frac{1}{4}$ d. 18141 d.
12) 54423
4535 3
£226 15 3

We may also find the amount in twopences, threepences, fourpences, or sixpences, by one division, and reduce these as directed in Case I.

CASE V. When the rate consists of pence and farthings, find the value of the pence, as directed in Case III., and that of the farthings from the proportion which they bear to the pounds. Add these together, and reduce.

Ex. 1st.] 3287 at 5 $\frac{1}{4}$ d.

At 4d. = $\frac{1}{2}$ of 1s. 1095 8
At 1d. = $\frac{1}{4}$ of 4d. 273 11
At 1f. = $\frac{1}{4}$ of 1d. 68 $\frac{5}{4}$
At 5 $\frac{1}{4}$ 1438 0 $\frac{3}{4}$
£71 18 0 $\frac{3}{4}$

Ex. 2d.] 4573 at 2 $\frac{3}{4}$ d.

At 2d. = $\frac{1}{6}$ of 1s. 762 2
At $\frac{1}{2}$ d. = $\frac{1}{4}$ of 2d. 190 $\frac{6}{2}$
At $\frac{1}{4}$ d. = $\frac{1}{2}$ of $\frac{1}{2}$ d. 95 $\frac{3}{4}$
At 2 $\frac{3}{4}$ 1047 11 $\frac{3}{4}$
£52 7 11 $\frac{3}{4}$

Ex. 3d.] 2842 at 3 $\frac{1}{2}$ d.

At 3d. = $\frac{1}{4}$ of 1s. 710 6
At 3f. = $\frac{1}{4}$ of 3d. 177 $\frac{7}{4}$
At 3 $\frac{1}{2}$ 888 1 $\frac{1}{2}$
£44 8 1 $\frac{1}{2}$

Ex. 4th.] 3572 at 7 $\frac{1}{2}$ d.

At 6d. = $\frac{1}{2}$ of 1s. 1786
At $\frac{1}{2}$ d. = $\frac{1}{4}$ of 6d. 446 6
At 7 $\frac{1}{2}$ 2232 6
£111 12 6

Here we suppose first 6d. and then 3d. to be paid for each article; half the quantity is the number of shillings they would cost at 6d. each, half of that is the cost at 3d., and these added and reduced give the answer.

Here we calculate what the articles would cost at 6d., at 3d., and at 2d., and add the values.

Practice. It is sometimes best to join some of the pence with the farthings in the calculation. Thus, in Ex. 4. we reckon the value at 6d. and at 3 halfpence, which makes $7\frac{1}{2}$.

If the rate be $1\frac{1}{2}$, which is an eighth part of a shilling, the value is found in shillings by dividing the quantity by 8.

CASE VI. When the rate consists of shillings and lower denominations.

Method 1. Multiply the quantity by the shillings, and find the value of the pence and farthings, if any, from the proportion they bear to the shillings. Add and reduce.

Ex. 1st, 4258 at 17s. 3d.

17s.	3d. = $\frac{1}{4}$ of 1s.
17s. 3d.	
17s.	3d. = $\frac{1}{4}$ of 1s.
17s. 3d.	

Ex. 2d, 5482 at 12s. $4\frac{1}{2}$ d.

12s.	3d. = $\frac{1}{4}$ of 1s.
12s.	$1\frac{1}{2}$ d. = $\frac{1}{2}$ of 3d.
12s. $4\frac{1}{2}$ d.	

Method 2. Divide the rate into aliquot parts of a pound; calculate the values corresponding to these, as directed in Case I., and add them.

Ex. 1st, 3894 at 17s. 6d. *Ex. 2d,* 1765 at 9s. 2d.

10s. = $\frac{1}{2}$	£1947	6s. 8d. = $\frac{1}{3}$	£588 6 8
5s. = $\frac{1}{4}$	973 10	2s. 6d. = $\frac{1}{8}$	220 12 6
2s. 6d. = $\frac{1}{8}$	486 15	9s. 2d. = $\frac{1}{10}$	£808 19 2
17s. 6d.	£3407 5		

Sometimes part of the value is more readily obtained from a part already found; and sometimes it is easiest to calculate at a higher rate, and subtract the value at the difference.

Ex. 3d, 63790 at 5s. 4d. *Ex. 4th,* 3664 at 14s. 9d.

4s. = $\frac{1}{2}$	£12758	10s. = $\frac{1}{2}$	£1832
1s. 4d. = $\frac{1}{3}$ of 4s.	4252 13 4	5s. = $\frac{1}{2}$ of 10s.	916
5s. 4d.	£17010 13 4	15s.	2748
		3d. = $\frac{1}{20}$ of 5s.	45 16
		14s. 9d.	£2702 4

Method 3. If the price contain a composite number of pence, we may multiply the value at a penny by the component parts.

Ex. 5628 at 2s. 11d. or 35d.

12)5628
20)469
£23 9
5
£117 5
7
£820 15

CASE VII. When the rate consists of pounds and lower denominations.

Method 1. Multiply by the pounds, and find the value of the other denominations from the proportion which they bear to the pounds.

Ex. 1st, 3592 at £3. 12s. 8d.

£3	12s. = $\frac{1}{5}$ of £3
8d. = $\frac{1}{18}$ of 12s.	
£3 12 8	

Ex. 2d, 543 at £2. 5s. $10\frac{1}{2}$ d. *Practice.*

£2	5s.	10d.	$\frac{1}{2}$ d.
£2	5s.	10d.	$\frac{1}{2}$ d.
£2	5s.	10d.	$\frac{1}{2}$ d.
£2	5s.	10d.	$\frac{1}{2}$ d.

Method 2. Reduce the pounds to shillings, and proceed as in Case VI.

Ex. 1st, 3592 at £3. 12s. 8d. *Ex. 2d,* 3683 at £2. 4s. 11d.

	<u>72</u>	<u>20</u>		<u>45</u>
	7184	72		18415
	<u>25144</u>			<u>14732</u>
	258624		At 45s.	165735
4d.= $\frac{1}{3}$ s.	1197	4	At 1d.= $\frac{1}{2}$ s.	307 11
4d.= $\frac{1}{3}$ s.	1197	4		
	<u>261018</u>	8	44s. 11d.	165427 0 1
8d.				£8271 7 1
	£13050	18 8		

We have hitherto explained the various methods of computation when the quantity is a whole number and in one denomination. It remains to give the proper directions when the quantity contains a fraction, or is expressed in several denominations.

When the quantity contains a fraction, work for the integers by the preceding rules, and for the fraction take proportional parts.

When the quantity is expressed by several denominations, and the rate given for the higher, calculate the higher, consider the lower one as fractions, and work by the last rule.

When the rate is given for the lower denomination, reduce the higher denomination to the lower, and calculate accordingly.

Note 1. 7 lb. 14 lb. and 21 lb. are aliquot parts of 1 qr.; and 16 lb. is $\frac{1}{4}$ of 1 cwt.; and are therefore easily calculated.

2. If the price of a dozen be so many shillings, that of an article is as many pence; and if the price of a gross be so many shillings, that of a dozen is as many pence.

3. If the price of a ton or score be so many pounds, that of 1 cwt., or a single article, is as many shillings.

4. Though a fraction less than a farthing is of no consequence, and may be rejected, the learner must be careful lest he lose more than a farthing, by rejecting several remainders in the same calculation.

SECT. II.—DEDUCTIONS ON WEIGHTS, &c.

The full weight of any merchandise, together with that of the cask, box, or other package, in which it is contained, is called the *gross weight*. From this we must make proper deductions in order to discover the quantity for which price or duty should be charged, which is called the *nett weight*.

Tare is the allowance for the weight of the package; and this should be ascertained by weighing it before the goods are packed. Sometimes, however, particularly in payment of duty, it is customary to allow so much per cwt. or so much per 100 lb. in place of tare.

Tret is an allowance of 4 lb. on 104 granted on currants and other goods on which there is waste, in order that the weight may answer when the goods are retailed.

Cloff or Draught is a further allowance granted on some goods in London of 2 lb. on every 3 cwt. to turn the scale in favour of the purchaser. The method of calculating these, and the like, will appear from the following examples.

Commis-
sion, &c.

Ex. 1st, What is the nett weight of 17 cwt. 2 q. 14 lb., tare 18 lb. per cwt.

	Cwt.	q.	lb.		Cwt.	q.	lb.
	17	2	14	gross, or	17	2	14
16 lb. = $\frac{1}{8}$ cwt.	2	2	2				6
2 lb. = $\frac{1}{4}$ of 16 lb.	1	7	$\frac{1}{4}$		105	3	—
18 lb.	2	3	9 $\frac{1}{4}$	tare			3
					317	1	—
	14	3	4 $\frac{3}{4}$	nett.	28	317	$\frac{1}{4}$ lb.
					4)	11	9 $\frac{1}{4}$ (2 3 9 $\frac{1}{4}$ tare.

In the first method we add the tare at 16 lb., which is $\frac{1}{8}$ of the gross weight, to the tare at 2 lb., which is $\frac{1}{4}$ of the former. In the second we multiply the gross weight by 18; the tare is 1 lb. for each cwt. of the product, and is reduced by division to higher denominations.

Ex. 2d, What is the tret of 158 cwt. 3 q. 4 lb.

	Cwt.	q.	lb.		Cwt.	q.	lb.
26)	158	3	4	(6 0 12 tret.			
	156						
	2						
	4			Because tret is always 4 lb. in 104, or 1 lb. in 26, it is obtained by dividing by 26.			
	11						
	28						
	312						
	312						

3d, What is the cloff on 28 cwt. 2 q. ?

Cwt.	q.
28	2
	2

3) 57 (19 lb.

This allowance being 2 lb. on every 3 cwt., might be found by taking $\frac{2}{3}$ of the number of cwts. and multiplying it by 2. It is better to begin with multiplication, for the reason given, p. 550, col. 2, par. 2.

SECT. III.—COMMISSION, &c.

It is frequently required to calculate allowances on sums of money, at the rate of so many per £100. Of this kind is COMMISSION, or the allowance due to a factor for buying or selling goods, or transacting any other business; PREMIUM OF INSURANCE, or allowance given for engaging to repay one's losses at sea or otherwise; EXCHANGE, or the allowance necessary to be added or subtracted for reducing the money of one place to that of another; PREMIUMS ON STOCK, or the allowance given for any share of a public stock above the original value. All these, and others of a like kind, are calculated by the following

RULE.—Multiply the sum by the rate, and divide the product by 100. If the rate contain a fraction, take proportional parts.

Ex. What is the commission on £728 at $2\frac{3}{4}$ per cent. ?

	728
	2
2 per cent.	1456
$\frac{1}{4}$	364
$\frac{1}{4}$	182
1 00)20 02	20
	40
	12
	4 80
	4
	Ans. £20 0 4 $\frac{1}{4}$
	3 20

When the rate is given in guineas, which is common in cases of insurance, you may add a twentieth part to the sum before you calculate; or you may calculate at an equal number of pounds, and add a twentieth part to the answer.

When the given sum is an exact number of 10 pounds, the calculation may be done without setting down any figures. Every £10 at $\frac{1}{2}$ per cent. is a shilling, and at other rates in proportion. Thus, £170 at $\frac{1}{2}$ per cent. is 17s., and at $\frac{1}{4}$ per cent. 8s. 6d.

SECT. IV.—INTEREST.

Interest is the allowance given for the use of money by the borrower to the lender. This is computed at so many pounds for each hundred lent for a year, and a like proportion for a greater or a less time. The highest rate is limited by our laws to 5 per cent. which is called the *legal interest*, and is due on all debts constituted by bond or bill, which are not paid at the proper term; and it is always understood when no other rate is mentioned.

The interest of any sum for a year, at any rate, is found by the method explained in the last section.

The interest of any number of pounds for a year at 5 per cent. is one twentieth part, or an equal number of shillings. Thus the interest of £34675 for a year is 34675 shillings.

The interest for a day is obtained by dividing the interest for a year by the number of days in a year. Thus the interest of £34675 for a day is found by dividing 34675 shillings by 365, and comes to 95 shillings.

The interest for any number of days is obtained by multiplying the daily interest by the number of days. Thus the interest of £34675 for 17 days is 17 times 95 shillings, or 1615 shillings; and this divided by 20, in order to reduce it, comes to £80. 15s.

It would have served the same purpose, and been easier, to multiply at first by 17, the number of days; and instead of dividing separately by 365, and by 20, to divide at once by 7300, the product of 365 multiplied by 20; and this division may be facilitated by the table inserted p. 549, col. 1.

The following practical rules may be inferred from the foregoing observations.

I. To calculate interest at 5 per cent.

Multiply the principal by the number of days, and divide the product by 7300.

II. To calculate interest at any other rate.

Find what it comes to at 5 per cent. and take a proper proportion of the same for the rate required.

 Interest at 4 per cent. £0 5 4

CHAP. VIII.—VULGAR FRACTIONS.

In order to understand the nature of vulgar fractions, we must suppose unity (or the number 1) divided into several equal parts. One or more of these parts is called a *fraction*, and is represented by placing one number in a small character above a line, and another under it: For example, two fifth parts is written thus, $\frac{2}{5}$. The number under the line (5) shows how many parts unity is divided into, and is called the *denominator*. The number above the line (2) shows how many of these parts are represented, and is called the *numerator*.

It follows, from the manner of representing fractions, that when the numerator is increased, the value of the fraction becomes greater; but when the denominator is increased, the value becomes less. Hence we may infer, that if the numerator and denominator be both increased, or both diminished, in the same proportion, the value is not altered; and therefore, if we multiply both by any number whatever, or divide them by any number which measures both, we shall obtain other fractions of equal value. Thus, every fraction may be expressed in a variety of forms, which have all the same signification.

A fraction annexed to an integer or whole number makes a mixed number; for example, five and two third parts, or $5\frac{2}{3}$. A fraction whose numerator is greater than its denominator is called an *improper fraction*; for example, seventeen third parts, or $\frac{17}{3}$. Fractions of this kind are greater than unity. Mixed numbers may be represented in the form of improper fractions, and improper fractions may be reduced to mixed numbers, and sometimes to integers. As fractions, whether proper or improper, may be represented in different forms, we must explain the method of reducing them from one form to another before we consider the other operations.

PROBLEM I.—To reduce mixed numbers to improper fractions.

Multiply the integer by the denominator of the fraction, and to the product add the numerator. The sum is the numerator of the improper fraction sought, and is placed above the given denominator.

Ex. $5\frac{2}{3} = \frac{17}{3}$.
 5 integer.
 3 denominator.
 15 product.
 2 numerator given.
 17 numerator sought.

Because one is equal to two halves, or 3 third parts, or 4 quarters, and every integer is equal to twice as many halves, or four times as many quarters, and so on, therefore, every integer may be expressed in the form of an improper fraction, having an assigned denominator. The numerator is obtained by multiplying the integer into the

denominator. Hence the reason of the foregoing rule is evident: 5 reduced to an improper fraction whose denominator is 3, makes $\frac{15}{3}$, and this added to $\frac{2}{3}$ amounts to $\frac{17}{3}$.

PROBLEM II.—To reduce improper fractions to whole or mixed numbers,

Divide the numerator by the denominator.

Ex. $\frac{112}{17} = 6\frac{10}{17}$.
 $17)112(6\frac{10}{17}$
 102
 10

This problem is the converse of the former, and the reason may be illustrated in the same manner.

PROBLEM III.—To reduce fractions to lower terms.

Divide both numerator and denominator by any number which measures both, and place the quotients in the form of a fraction.

Example. $\frac{135}{360} = \frac{27}{72} = \frac{3}{8}$.

Here we observe that 135 and 360 are both measured by 5, and the quotients form $\frac{27}{72}$, which is a fraction of the same value as $\frac{135}{360}$ in lower terms. Again, 27 and 72 are both measured by 9, and the quotients form $\frac{3}{8}$, which is still of equal value, and in lower terms.

It is generally sufficient, in practice, to divide by such measures as are found to answer on inspection, or by the rules given p. 547, col. 2. But if it be required to reduce a fraction to the lowest possible terms, we must divide the numerator and denominator by the greatest number which measures both. What number this is may not be obvious, but will always be found by the following rule.

To find the greatest common measure of two numbers, divide the greater by the lesser and the divisor by the remainder continually till nothing remains; the last divisor is the greatest common measure.

Ex. Required the greatest number which measures 475 and 589?

$$\begin{array}{r}
 475)589(1 \\
 \quad 475 \\
 \quad \hline
 \quad 114)475(4 \\
 \quad \quad 456 \\
 \quad \quad \hline
 \quad \quad 19)114(6 \\
 \quad \quad \quad 114 \\
 \quad \quad \quad \hline
 \quad \quad \quad 0
 \end{array}$$

Here we divide 589 by 475, and the remainder is 114; then we divide 475 by 114, and the remainder is 19; then we divide 114 by 19, and there is no remainder; from which we infer that 19, the last divisor, is the greatest common measure.

To explain the reason of this, we must observe, that any number which measures two others will also measure their sum and their difference, and will measure any multiple of either. In the foregoing example, any number which measures 589 and 475 will measure their difference, 114, and will measure 456, which is a multiple of 114; and any number which measures 475 and 456 will also measure their difference, 19. Consequently, no number greater than 19 can measure 589 and 475. Again, 19 will measure them both, for it measures 114, and therefore measures 456, which is a multiple of 114 and 475, which is just 19 more than 456; and because it measures 475 and 114, it will measure their sum, 589. To reduce $\frac{475}{589}$ to the lowest possible terms, we divide both numbers by 19, and it comes to $\frac{25}{31}$.

If there be no common measure greater than 1, the fraction is already in the lowest terms.

If the greatest common measure of 3 numbers be required, we find the greatest measure of the two first, and then the greatest measure of that number and the third. If there be more numbers, we proceed in the same manner.

PROBLEM IV.—To reduce fractions to others of equal value that have the same denominator.

1st, *Multiply the numerator of each fraction by all the deno-*

Vulgar Fractions.

Vulgar Fractions. 3d, To multiply a mixed number by a fraction, we may multiply the integer by the fraction, and the two fractions together, and add the products.

$$\begin{aligned} \text{Ex. } 15\frac{5}{8} \times \frac{2}{9} &= 3\frac{5}{12} \\ 15 \times \frac{2}{9} &= 3\frac{2}{3} = 3\frac{4}{6} \\ \frac{5}{8} \times \frac{2}{9} &= \frac{10}{72} = \frac{5}{36} = \frac{1}{7.2} \\ &= 3\frac{4}{6} + \frac{1}{7.2} = 3\frac{4}{6} + \frac{1}{7.2} \end{aligned}$$

4th, When both factors are mixed numbers, we may multiply each part of the multiplicand, first by the integer of the multiplier, and then by the fraction, and add the four products.

$$\begin{aligned} \text{Ex. } 8\frac{2}{3} \text{ by } 7\frac{3}{4} & \\ 8 \times 7 &= 56 \\ 8 \times \frac{3}{4} &= 6 \text{ by Prob. II.} \\ \frac{2}{3} \times 7 &= 4\frac{2}{3} = 4\frac{4}{6} \\ \frac{2}{3} \times \frac{3}{4} &= \frac{2}{4} = \frac{1}{2} \\ &= 2\frac{1}{2} + \frac{1}{2} = 3 \\ \text{product } 65\frac{2}{3} &\text{ as before.} \end{aligned}$$

SECT. IV.—DIVISION OF VULGAR FRACTIONS.

RULE I.—Multiply the numerator of the dividend by the denominator of the divisor. The product is the numerator of the quotient.

II.—Multiply the denominator of the dividend by the numerator of the divisor. The product is the denominator of the quotient.

$$\begin{aligned} \text{Ex. Divide } \frac{2}{9} \text{ by } \frac{7}{9} & \quad \text{quotient } \frac{13}{35}. \\ 2 \times 9 &= 18 \\ 5 \times 7 &= 35. \end{aligned}$$

To explain the reason of this operation, let us suppose it required to divide $\frac{2}{9}$ by $\frac{7}{9}$, or to take one seventh part of that fraction. This is obtained by multiplying the denominator by 7; for the value of fractions is diminished by increasing their denominators, and comes to $\frac{2}{63}$. Again, because $\frac{7}{9}$ is nine times less than seven, the quotient of any number divided by $\frac{7}{9}$ will be nine times greater than the quotient of the same number divided by 7. Therefore we multiply $\frac{2}{63}$ by 9, and obtain $\frac{18}{63}$.

If the divisor and dividend have the same denominator, it is sufficient to divide the numerators.

$$\text{Ex. } \frac{12}{7} \text{ divided by } \frac{3}{7} \text{ quotes } 4.$$

The foregoing rule may be extended to every case by reducing integers and mixed numbers to the form of improper fractions. We shall add some directions for shortening the operation when integers and mixed numbers are concerned.

1st, When the dividend is an integer, multiply it by the denominator of the divisor, and divide the product by the numerator.

$$\text{Ex. Divide } 368 \text{ by } \frac{7}{4}$$

$$5)2576(515\frac{1}{5} \text{ quotient.}$$

2d, When the divisor is an integer, and the dividend a fraction, multiply the denominator by the divisor, and place the product under the numerator.

$$\text{Ex. Divide } \frac{8}{9} \text{ by } 5 \quad \text{quotient } \frac{8}{45}$$

$$8 \times 5 = 40$$

3d, When the divisor is an integer, and the dividend a mixed number, divide the integer, and annex the fraction to the remainder; then reduce the mixed number thus formed to an improper fraction, and multiply its denominator by the divisor.

$$\begin{aligned} \text{Ex. To divide } 576\frac{4}{11} \text{ by } 7 & \quad \text{quotient } 82\frac{26}{77} \\ 7)576(82 & \\ 56 & \\ \underline{16} & \\ 14 & \\ \underline{24} &= \frac{26}{11} \\ 11 \times 7 &= 77 \end{aligned}$$

Here we divide 576 by 7, the quotient is 82, and the remainder 2, to which we annex the fraction $\frac{4}{11}$, and reduce $2\frac{4}{11}$ to an improper fraction $\frac{26}{11}$, and multiply its denominator by 7, which gives $\frac{182}{77}$.

Vulgar Fractions. Hitherto we have considered the fractions as abstract numbers, and laid down the necessary rules accordingly. We now proceed to apply these to practice. Shillings and pence may be considered as fractions of pounds, and lower denominations of any kind as fractions of higher; and any operation, where different denominations occur, may be wrought by expressing the lower ones in one form of vulgar fractions, and proceeding by the following rules. For this purpose the two following problems are necessary.

PROBLEM V.—To reduce lower denominations to fractions of higher.

Place the given number for the numerator, and the value of the higher for the denominator.

Examples.

1. Reduce 7d. to the fraction of a shilling. Ans. $\frac{7}{12}$.
2. Reduce 7d. to a fraction of a pound. Ans. $\frac{7}{240}$.
3. Reduce 15s. 7d. to a fraction of a pound. Ans. $\frac{157}{240}$.

PROBLEM VI.—To value fractions of higher denominations.

Multiply the numerator by the value of the given denomination, and divide the product by the denominator; if there be a remainder, multiply it by the value of the next denomination, and continue the division.

$$\begin{aligned} \text{Ex. 1st, Required the value} & \quad 2d, \text{ Required the value} \\ \text{of } \frac{17}{60} \text{ of L1.} & \quad \text{of } \frac{8}{9} \text{ of 1 cwt.} \\ \begin{array}{r} 20 \\ 60)340(5 \quad s. \quad d. \\ 300 \\ \underline{40} \\ 12 \\ 60)480 \\ 480 \end{array} & \quad \begin{array}{r} 4 \\ 9)32(3 \quad qrs. \quad lb. \\ 27 \\ \underline{5} \\ 28 \\ 9)140 \\ 9 \\ \underline{50} \\ 45 \\ 5 \end{array} \end{aligned}$$

In the first example we multiply the numerator 17 by 20, the number of shillings in a pound, and divide the product, 340, by 60, the denominator of the fraction, and obtain a quotient of 5 shillings; then we multiply the remainder, 40, by 12, the number of pence in a shilling, which produces 480, which, divided by 60, quotes 8d. without a remainder. In the second example we proceed in the same manner; but as there is a remainder, the quotient is completed by a fraction.

Sometimes the value of the fraction does not amount to an unit of the lowest denomination; but it may be reduced to a fraction of that or any other denomination by multiplying the numerator according to the value of the places. Thus $\frac{1}{1289}$ of a pound is equal to $\frac{12}{1289}$ of a shilling, or $\frac{240}{1289}$ of a penny, $\frac{960}{1289}$ of a farthing.

CHAP. IX.—DECIMAL FRACTIONS.

SECT. I.—NOTATION AND REDUCTION.

Decimal fractions are such as have 10, or some power of 10 (that is 100, 1000, &c.), for a denominator: such are these,—

$$\frac{5}{10}, \quad \frac{24}{100}, \quad \frac{75}{1000}, \quad \frac{462}{100000};$$

They are more simply written thus:

$$.5, \quad .24, \quad .075, \quad .00462;$$

the number of figures after the point being always the same as the number of ciphers in the denominators.

In decimal fractions, as thus written, the figure next

Decimal Fractions. the point, to the right, indicates so many tenths; the next so many hundredths, and so on. Thus, in the fraction $\cdot 346$, the figure 3 expresses 3 tenths, 4 denotes 4 hundredths, and 6, 6 thousandths.

The use of ciphers in decimals, as well as in integers, is to bring the significant figures to their proper places, on which their value depends. As ciphers, when placed on the left hand of an integer, have no signification, but, when placed on the right hand, increase the value ten times each; so ciphers, when placed on the right hand of a decimal, have no signification, but when placed on the left hand, diminish the value ten times each.

The notation and numeration of decimals will be obvious from the following examples:

4·7 signifies four, and seven tenth parts.
 $\cdot 47$ four tenth parts, and seven hundredth parts, or 47 hundredth parts.
 $\cdot 047$ four hundredth parts, and seven thousandth parts, or 47 thousandth parts.
 $\cdot 407$ four tenth parts, and seven thousandth parts, or 407 thousandth parts.
 4·07 four, and seven hundredth parts.
 4·007 four, and seven thousandth parts.

To reduce vulgar fractions to decimal ones. *Annex a cipher to the numerator, and divide it by the denominator, annexing a cipher continually to the remainder.*

$\begin{array}{r} \text{Ex. 1st, } \frac{12}{75} = \cdot 16 \\ 75 \overline{)120(16} \\ \underline{75} \\ 450 \\ \underline{450} \\ 450 \end{array}$	$\begin{array}{r} \text{2d, } \frac{5}{64} = \cdot 078125 \\ 64 \overline{)500(078125} \\ \underline{448} \\ 520 \\ \underline{512} \\ 80 \\ \underline{64} \\ 160 \\ \underline{128} \\ 320 \\ \underline{320} \end{array}$	$\begin{array}{r} \text{3d, } \frac{2}{3} = \cdot 666 \\ 3 \overline{)20(666} \\ \underline{18} \\ 20 \\ \underline{18} \\ 20 \\ \underline{18} \\ 20 \end{array}$
$\begin{array}{r} \text{4th, } \frac{5}{6} = \cdot 833 \\ 6 \overline{)50(833} \\ \underline{48} \\ 20 \\ \underline{18} \\ 20 \\ \underline{18} \\ 20 \end{array}$	$\begin{array}{r} \text{5th, } \frac{7}{27} = \cdot 259 \\ 27 \overline{)70(259} \\ \underline{54} \\ 160 \\ \underline{135} \\ 250 \\ \underline{243} \\ 7 \end{array}$	$\begin{array}{r} \text{6th, } \frac{7}{22} = \cdot 31818 \\ 22 \overline{)70(31818} \\ \underline{66} \\ 40 \\ \underline{22} \\ 180 \\ \underline{176} \\ 40 \\ \underline{22} \\ 18 \end{array}$

The reason of this operation will be evident, if we consider that the numerator of a vulgar fraction is understood to be divided by the denominator; and this division is actually performed when it is reduced to a decimal.

In like manner, when there is a remainder left in division, we may extend the quotient to a decimal, instead of completing it by a vulgar fraction, as in the following example:

$$\begin{array}{r} 25 \overline{)646(25\frac{21}{25} \text{ or } 25\cdot 84.} \\ \underline{50} \\ 146 \\ \underline{125} \\ \text{Rem. } 21\cdot 0 \\ \underline{200} \\ 100 \\ \underline{100} \end{array}$$

From the foregoing examples we may distinguish the several kinds of decimals. Some vulgar fractions may be reduced exactly to decimals, as Ex. 1st and 2d, and are

called *terminate* or *finite decimals*. Others cannot be exactly reduced, because the division always leaves a remainder; but, by continuing the division, we will perceive how the decimal may be extended to any length whatever. These are called *infinite decimals*. If the same figure continually returns, as in Ex. 3d and 4th, they are called *repeaters*. If two or more figures return in their order, they are called *circulates*. If this regular succession go on from the beginning, they are called *pure repeaters*, or *circulates*, as Ex. 3d and 5th. If otherwise, as Ex. 4th and 6th, they are mixed *repeaters* or *circulates*, and the figures prefixed to those in regular succession are called the *finite part*. Repeating figures are generally distinguished by a dash, and circulates by a comma or other mark, at the beginning and end of the circle; and the beginning of a repeater or circulate is pointed out in the division by an asterisk.

Lower denominations may be considered as fractions of higher ones, and reduced to decimals accordingly. We may proceed by the following rule, which is the same in effect as the former.

To reduce lower denominations to decimals of higher. *Annex a cipher to the lower denomination, and divide it by the value of the higher. When there are several denominations, begin at the lowest, and reduce them in their order.*

Ex. To reduce 5 cwt. 2 qr. 21 lb. to a decimal of a ton.

$\begin{array}{r} 28 \overline{)210(75} \\ \underline{196} \\ 140 \\ \underline{140} \end{array}$	$\begin{array}{r} 4 \overline{)275(6875} \\ \underline{24} \\ 35 \\ \underline{32} \\ 28 \\ \underline{20} \\ 20 \end{array}$	$\begin{array}{r} 20 \overline{)56875(284375} \\ \underline{40} \\ 168 \\ \underline{160} \\ 87 \\ \underline{80} \\ 75 \\ \underline{60} \\ 150 \\ \underline{140} \\ 100 \\ \underline{100} \end{array}$
---	--	--

Here, in order to reduce 21 lb. to a decimal of 1 qr. we annex a cipher, and divide by 28, the value of 1 qr. This gives $\cdot 75$. Then we reduce 2·75 qrs. to a decimal of 1 cwt. by dividing by 4, the value of 1 cwt., and it comes to $\cdot 6875$. Lastly, 5·6875 cwt. is reduced to a decimal of a ton by dividing by 20, and comes to $\cdot 284375$.

To value a decimal fraction. *Multiply it by the value of the denomination, and cut off as many decimal places from the product as there are in the multiplicand. The rest are integers of the lower denomination.*

Example. What is the value of $\cdot 425$ of £1?

$$\begin{array}{r} \cdot 425 \\ \underline{20} \\ \text{sh. } 8\cdot 500 \\ \underline{6} \\ \text{d. } 3\cdot 000 \end{array}$$

SECT. II.—ARITHMETIC OF TERMINATE DECIMALS.

The value of decimal places decreases like that of integers, ten of the lower place in either being equal to one of the next higher; and the same holds in passing from decimals to integers. Therefore, all the operations are performed in the same way with decimals, whether placed by themselves or annexed to integers, as with pure integers. The only peculiarity lies in the arrangement and pointing of the decimals.

In addition and subtraction, *Arrange units under units, tenth parts under tenth parts, and proceed as in integers.*

Decimal
Fractions.

32-035	from 13-348	and 12-248
116-374	take 9-2993	10-6752
160-63		
12-3645	4-0487	1-5728
321-4035		

Ex. 625)9375(15
625
3125
3125
0

9375	Decimal Fractions.
·0016	
56250	
9375	
15-0000	

In multiplication, *Allow as many decimal places in the product as there are in both factors. If the product has not so many places, supply them by prefixing ciphers on the left hand.*

Ex. 1st, 1-37	2d, 43-75	3d, 1-572
1-8	48	12
1096	35000	018864
137	17500	
2-466	21-0000	

The reason of this rule may be explained, by observing, that the value of the product depends on the value of the factors; and since each decimal place in either factor diminishes its value ten times, it must equally diminish the value of the product.

To multiply decimals by 10, move the decimal point one place to the right; to multiply by 100, 1000, or the like, move it as many places to the right as there are ciphers in the multiplier.

In division, *Point the quotient so that there may be an equal number of decimal places in the dividend as in the divisor and quotient together.*

Therefore, if there be the same number of decimal places in the divisor and dividend, there will be none in the quotient.

If there be more in the dividend, the quotient will have as many as the dividend has more than the divisor.

If there be more in the divisor, we must annex (or suppose annexed) as many ciphers to the dividend as may complete the number in the divisor, and all the figures of the quotient are integers.

If the division leave a remainder, the quotient may be extended to more decimal places; but these are not regarded in fixing the decimal point.

The reason for fixing the decimal point as directed may be inferred from the rule followed in multiplication. The quotient multiplied by the divisor produces the dividend; and therefore the number of decimal places in the dividend is equal to those in the divisor and quotient together.

The first figure of the quotient is always at the same distance from the decimal point, and on the same side, as the figure of the dividend which stands above the unit place of the first product. This also takes place in integers; and the reason is the same in both.

Multiplication by fractions corresponds with division by integers, and division by fractions with multiplication by integers; when we multiply by $\frac{1}{2}$ or $\cdot 5$, we obtain the same answer as when we divide by 2, and every integer has a correspondent decimal, which may be called its *reciprocal*. Multiplication by that decimal supplies the place of division by the integer, and division supplies the place of multiplication.

To find the reciprocal of any number, divide 1 with ciphers annexed by that number.

Ex. Required the reciprocal of 625.

625)1-000(·0016
625
3750
3750
0

The product of any number multiplied by $\cdot 0016$ is the same as the quotient divided by 625.

Because $\cdot 0016$ is $\frac{1}{625}$ of unity, any number multiplied by that fraction will be diminished 625 times. For a like reason, the quotient of any number divided by $\cdot 0016$ will be equal to the product of the same multiplied by 625.

Ex. $\cdot 0016)516-0000(322300$	516
48 · · · ·	625
36	2580
32	1032
40	3096
32	322500
80	
80	
0	

SECT. III.—APPROXIMATE DECIMALS.

It has been shown that some decimals, though extended to any length, are never complete; and others, which terminate at last, sometimes consist of so many places that it would be difficult in practice to extend them fully. In these cases, we may extend the decimal to three, four, or more places, according to the nature of the articles and the degree of accuracy required, and reject the rest of it as inconsiderable. In this manner we may perform any operation with ease by the common rules, and the answers we obtain are sufficiently exact for any purpose in business. Decimals thus restricted are called *approximates*.

Shillings, pence, and farthings, may be easily reduced to decimals of three places by the following rule: Take half the shillings for the first decimal place, and the number of farthings increased by one, if it amount to 24 or upwards; by two, if it amount to 48 or upwards; and by three, if it amount to 72 or upwards, for the two next places.

The reason of this is, that 20 shillings make a pound, two shillings is the tenth part of a pound, and therefore half the number of shillings makes the first decimal place. If there were 50 farthings in a shilling, or 1000 in a pound, the units of the farthings in the remainder would be thousandth parts, and the tens would be hundredth parts, and so would give the two next decimal places; but because there are only 48 farthings in a shilling, or 960 in a pound, every farthing is a little more than the thousandth part of a pound; and since 24 farthings make 25 thousandth parts, allowance is made for that excess by adding 1 for every 24 farthings, as directed.

If the number of farthings be 24, 48, or 72, and consequently the second and third decimal places 25, 50, and 75, they are exactly right; otherwise they are not quite complete, since there should be an allowance of $\frac{1}{24}$, not only for 24, 48, and 72 farthings, but for every other single farthing. They may be completed by the following rule: multiply the second and third decimal places, or their excess above 25, 50, 75, by 4. If the product amount to 24 or upwards, add 1; if 48, add 2; if 72, add 3. By this operation we obtain two decimal places more; and by continuing the same operation, we may extend the decimal till it terminate in 25, 50, 75, or in a repeater.

Decimals of sterling money of three places may easily be reduced to shillings, pence, and farthings, by the following rule: Double the first decimal place, and if the second be 5 or upwards, add 1 thereto for shillings. Then divide the second and third decimal places, or their excess above 50, by 4, first deducting 1, if it amount to 25

Decimal Fractions. or upwards; the quotient is pence, and the remainder farthings.

As this rule is the converse of the former one, the reason of the one may be inferred from that of the other. The value obtained by it, unless the decimal terminate in 25, 50, or 75, is a little more than the true value; for there should be a deduction, not only of 1 for 25, but a little deduction of $\frac{1}{25}$ on the remaining figures of these places.

We proceed to give some examples of the arithmetic of approximates, and subjoin any necessary observations.

ADDITION.			SUBTRACTION.		
Cwt.	qrs.	lb.	Cwt.	qrs.	lb.
3	2	14	3	2	2 = 3·51785
2	3	22	1	1	19 = 1·41964
3	3	19	2	-	11 = 2·09821
4	1	25			

14 3 24 14·96427

If we value the sum of the approximates, it will fall a little short of the sum of the articles, because the decimals are not complete.

It is proper to add 1 to the last decimal place of the approximate, when the following figure would have been 5 or upwards. Thus the full decimal of 3 qrs. 22 lb. is ·946,428571, and therefore ·94643 is nearer to it than ·946,42. Approximates thus regulated will give exacter answers, sometimes above the true one and sometimes below it.

The mark + signifies that the approximate is less than the exact decimal, or requires something to be added. The mark — signifies that it is greater, or requires something to be subtracted.

MULTIPLICATION.		
Meth. 1st,	Meth. 2d,	Meth. 3d,
8278 +	8278	8278
2153 +	2153	3512
24834	16556	16556
41390	8278	827
8278	41390	413
16556	24834	24
17822534	17822534	1782

Here the last four places are quite uncertain. The right-hand figure of each particular product is obtained by multiplying 8 into the figures of the multiplier; but if the multiplicand had been extended, the carriage from the right-hand place would have been taken in; consequently the right-hand place of each particular product, and the four places of the total product, which depend on these, are quite uncertain. Since part of the operation therefore is useless, we may omit it; and for this purpose it will be convenient to begin (as in p. 547, col. 1, *fifth variety*) at the highest place of the multiplier. We may perceive that all the figures on the right hand of the line in Meth. 2 serve no purpose, and may be left out if we only multiply the figures on the multiplicand, whose products are placed on the left hand of the line. This is readily done by inverting the multiplier in Meth. 3, and beginning each product with the multiplication of that figure which stands above the figure of the multiplier that produces it, and including the carriage from the right-hand place.

If both factors be approximates, there are at least as many uncertain places in the product as in the longest factor. If only one be an approximate, there are as many uncertain places as there are figures in that factor, and sometimes a place or two more, which might be affected by the carriage. Hence we may infer how far it is necessary to extend the approximates in order to obtain the requisite number of certain places in the product.

DIVISION.

·3724 —	798 64237 +	(2144 or 37/24) 79864237(2144
744 8		7448
53 84		538
37 24		372
16 602		166
14 896		148
1 7063		18
14 896		14
2167		4

Here all the figures on the right hand of the line are uncertain, for the right-hand figure of the first product 7448 might be altered by the carriage if the divisor were extended; and all the remainders and dividends that follow are thereby rendered uncertain. We may omit these useless figures, for which purpose we dash a figure on the right hand of the divisor at each step, and neglect it when we multiply by the figure of the quotient next obtained; but we include the carriage. The operation, and the reason of it, will appear clear, by comparing the operation at large, and contracted, in the above example.

CHAP. X.—INTERMINATE DECIMALS.

SECT. 1.—REDUCTION OF INTERMINATE DECIMALS.

We have seen that some vulgar fractions admit of being converted into exact decimal fractions, while others have not that property, but proceed interminably, the numerator being either the same figure, or else a combination of figures always repeated. The fraction $\frac{5}{8}$ is of the first mentioned kind, its decimal value being $\frac{575}{1000}$, that is ·375; again, $\frac{1}{3}$ = ·333, &c. and $\frac{4}{7}$ = ·714285, 714285, &c. are examples of the second kind. Let us suppose a fraction reduced to its lowest terms, $\frac{3}{8}$, for example. Now, to convert this into a decimal, we annex ciphers to the numerator (that is, we multiply it by some power of 10), and divide by the denominator, the decimal denominator being always that power of ten by which the numerator was multiplied. In the case of $\frac{3}{8}$, the numerator is multiplied by 1000, which is exactly divisible by 8; for when the numbers are expressed by the product of their simple factors, we have $1000 = 2 \times 2 \times 2 \times 5 \times 5 \times 5$ and $8 = 2 \times 2 \times 2$, and $\frac{1000}{8} = 5 \times 5 \times 5 = 125$, therefore the decimal value of $\frac{3}{8}$ is $\frac{375}{1000}$, that is, ·375. Here it appears that the decimal fraction has a finite form, because the divisors of the denominator of the vulgar fraction are also divisors of a power of 10.

A like remark may be made concerning the fraction $\frac{7}{25} = \frac{7}{5 \times 5}$, the two equal divisors 5 being divisors of 10, and therefore their product a divisor of 100, and the fraction = ·28.

In general, it appears that if the simple factors of the denominators of a vulgar fraction be all either 2 or 5, its decimal value will be finite, otherwise not.

The fraction $\frac{1}{3}$ is therefore, from its nature, incapable of being converted into a finite decimal; but this fraction, when converted into a decimal, being ·1111, &c. *ad infinitum*, therefore $\frac{2}{3}$ will be ·222, &c. and $\frac{4}{3} = \frac{1}{3} = ·333$, &c. and so on to $\frac{8}{3}$, which will be ·888, &c. Hence it is manifest that every repeating decimal is equivalent to a vulgar fraction whose denominator is 9.

Again, since $\frac{1}{9} = ·010101$, &c. *ad infinitum*, therefore $\frac{2}{9} = ·0202$, &c.; and in like manner $\frac{17}{9} = ·1717$, &c. and so on, from $\frac{1}{9}$ to $\frac{89}{9}$, which is equal to ·89, 89, 89, &c. Therefore every circulating decimal of two figures is convertible into a vulgar fraction whose denominator is 99.

And since $\frac{1}{999} = ·001001001$, &c., therefore any fraction whose numerator consists of three figures, and deno-

Decimal Fraction

Decimal
Fractions minator 999, must produce a circulate of three figures; for example, $\frac{365}{999} = .365365365$, &c.; and in like manner, since $\frac{1}{999} = .0010001$, &c., therefore every fraction whose numerator consists of not more than four figures, and which has 9999 for a denominator, must produce a circulate of four figures, and so on.

It is now sufficiently manifest that all circulating decimals may be generated from vulgar fractions whose denominators are formed by a repetition of the figure 9; and hence it follows that every circulate may be converted into a vulgar fraction of that form.

RULES for reducing interminate decimals to vulgar fractions.

I. If the decimal be a pure repeater, place the repeating figure for the numerator, and 9 for the denominator.

II. If the decimal be a pure circulate, place the circulating figures for the numerator, and as many 9's as there are places in the circle for the denominator.

III. If there be ciphers prefixed to the repeating or circulating figures, annex a like number to the 9's in the denominator.

IV. If the decimal be mixed, subtract the finite part from the whole decimal. The remainder is the numerator, and the denominator consists of as many 9's as there are places in the circle, together with as many ciphers as there are finite places before the circle.

Thus, $\cdot 235,62 = \frac{23562}{100000}$

From the whole decimal	23562
We subtract the finite part	235

and the remainder $\frac{23327}{100000}$ is the numerator.

The reason may be illustrated by dividing the decimal into two parts, whereof one is finite, and the other a pure repeater or circulate, with ciphers prefixed. The sum of the vulgar fractions corresponding to these will be the value of the decimal sought.

and $\cdot 000,62 = \frac{62}{99000}$ by Rules II, III.

In order to add these vulgar fractions, we reduce them to a common denominator; and for that purpose we multiply both terms of the former by 99, which gives $\frac{23265}{99000}$; then we add the numerators.

235, or, by method explained p. 546, col. 1, par. 3,

<u>2115</u>	23500	Sum of numerators.
2115	235	23265 or 23562
<u>23265</u>	<u>23265</u>	62 235
		<u>23327</u> <u>23327</u>

The value of circulating decimals is not altered though one or more places be separated from the circle and considered as a finite part, providing the circle be completed. For example, $\cdot 27$ may be written $\cdot 272, \frac{270}{990}$, or $\frac{27}{99}$, which is also the value of $\cdot 27$; and if two or more circles be joined, the value of the decimal is still the same. Thus, $\cdot 2727 = \frac{2727}{9999}$, which is reduced by dividing the terms by 101 to $\frac{27}{99}$.

All circulating decimals may be reduced to a similar form, having a like number both of finite and circulating places. For this purpose, we extend the finite part of each as far as the longest, and then extend all the circles to so many places as may be a multiple of the number of places in each.

Ex. 34,725, extended, 34,725725725725
1,4562, 14.562456245624

Here the finite part of both is extended to two places, and the circle to 12 places, which is the least multiple for circles of 3 and 4 places.

SECT. II.—ADDITION AND SUBTRACTION OF INTERMEDIATE DECIMALS.

To add repeating decimals. *Extend the repeating figures one place beyond the longest finite ones, and when you add the right-hand column, carry to the next by 9.*

$$\begin{array}{r} \text{Ex. } 37524 \text{ or } 37524 \\ 8 8888\$ \\ 643 643 \\ 73 7333\$ \\ \hline 264046 \end{array}$$

To subtract repeating decimals. *Extend them as directed for addition, and borrow at the right-hand place, if necessary, by 9.*

<i>Ex. 1st,</i>	•9356¢	<i>Ex. 2d,</i>	•646
	•8473¢		•5342¢
	•0882¢		•1117¢

The reason of these rules will be obvious, if we recollect that repeating figures signify ninth parts. If the right-hand figure of the sum or remainder be 0, the decimal obtained is finite; otherwise it is a repeater.

To add circulating decimals. *Extend them till they become similar* (p. 563, col. 1, par. ult. &c.); and when you add the right-hand column, include the figure which would have been carried if the circle had been extended farther.

<i>Ex. 1st.</i>	<i>Extended.</i>	<i>Ex. 2d.</i>	<i>Extended.</i>
•574,	•574,574,	•874,	•874,874874,
•2,698,	•269,869,	•1463	•146,333333,
•428	•428	•1,58,	•158,585858,
•37,983	•379,839,	•32,	•323,232323,
	1•652,284,		1•503,026390,

Note 1. Repeaters mixed with circulates are extended and added as circulates.

Note 2. Sometimes it is necessary to inspect two or more columns for ascertaining the carriage; because the carriage from a lower column will sometimes raise the sum of the higher, so as to alter the carriage from it to a new circle. This occurs in Ex. 2.

Note 3. The sum of the circles must be considered as a similar circle. If it consist entirely of ciphers, the amount is terminate. If all the figures be the same, the amount is a repeater. If they can be divided into parts exactly alike, the amount is a circle of fewer places; but, for the most part, the circle of the sum is similar to the extended circles.

To subtract circulating decimals. *Extend them till they become similar; and when you subtract the right-hand figure, consider whether 1 would have been borrowed if the circles had been extended farther, and make allowance accordingly.*

$$\begin{array}{r} \begin{array}{l} \cdot 5,72, \quad \cdot 974, \quad \text{or} \quad \cdot 974974, \quad \cdot 8,135, \quad \text{or} \quad \cdot 8,135135, \\ \cdot 4,86, \quad \cdot 86, \quad \cdot 868686, \quad \cdot 452907, \quad \text{or} \quad \cdot 4,529074, \\ \hline \cdot 0,85, \quad \cdot 106288, \quad \cdot 3,606060, \\ \hline \text{or} \quad \cdot 3.60 \end{array} \end{array}$$

SECT. III.—MULTIPLICATION OF INTERMINATE DECIMALS.

CASE I.—When the multiplier is finite and the multiplicand repeats, carry by 9 when you multiply the repeating figure; the right-hand figure of each line of the product is a repeater, and they must be extended and added accordingly.

$$\begin{array}{r} \text{Ex. } 13494 \\ \quad \cdot 367 \\ \hline 94461 \\ 809666 \\ 4048333 \\ \hline \cdot 04952461 \end{array}$$

If the sum of the right-hand column be an even number of 9's, the product is finite; otherwise it is a repeater.

CASE II.—When the multiplier is finite, and the multiplicand circulates, add to each product of the right-hand figure the carriage which would have been brought to it if the circle had been extended. Each line of the product is a circle similar to the multiplicand, and therefore they must be extended and added accordingly.

The product is commonly a circulate similar to the

Decimal Fractions.

Decimal multiplicand; sometimes it circulates fewer places, repeats or becomes finite; it never circulates more places.

$$\text{Ex. } .37,46, \times .235$$

$$\begin{array}{r} .235 \\ 187,32, \\ 1123,93, \\ 7492,92, \\ \hline .08804,19, \end{array}$$

CASE III.—When the multiplier repeats or circulates, find the product as in infinite multipliers, and place under it the products which would have arisen from the repeating or circulating figures if extended.

$$\begin{array}{r} \text{Ex. 1st, } .958 \times .\text{\textcircled{8}} \qquad 2d, .784 \times .36, \\ \begin{array}{r} .8 \\ 7664 \\ 7664 \\ 7664 \\ 7664 \\ \hline 7664 \\ 7664 \\ \hline 7664 \end{array} \qquad \begin{array}{r} .36, \\ 4704 \\ 2352 \\ 28224 \\ 28224 \\ \hline 28224 \\ 28224 \\ \hline 28224 \end{array} \\ \hline .8515 \qquad 285,09, \end{array}$$

It is evident, that if a repeating multiplier be extended to any length, the product arising from each figure will be the same as the first, and each will stand one place to the right hand of the former. In like manner, if a circulating multiplier be extended, the product arising from each circle will be alike, and will stand as many places to the right hand of the former as there are figures in the circle. In the foregoing examples there are as many of these products repeated as is necessary for finding the total product. If we place down more, or extend them farther, it will only give a continuation of the repeaters or circulates.

The multiplication of interminate decimals may be often facilitated by reducing the multiplier to a vulgar fraction, and proceeding as directed p. 558, col. 2, par 8. Thus,

$$\begin{array}{r} 3d, .3824 \times .\text{\textcircled{7}} = \frac{7}{9} \qquad 4th, .384 \times .23 = \frac{23}{90} \\ \begin{array}{r} 7 \\ 9)2-6768 \\ \hline .2974\text{\textcircled{8}} \end{array} \qquad \begin{array}{r} 23 \\ 90)8-832 \\ \hline .0981\text{\textcircled{8}} \end{array} \end{array}$$

Therefore, in order to multiply by $\text{\textcircled{8}}$, we take one third part of the multiplier; and, to multiply by $\text{\textcircled{6}}$, we take two thirds of the same. Thus,

$$\begin{array}{r} 5th, .784 \times .\text{\textcircled{8}} = \frac{1}{3} \qquad 6th, .8761 \times .\text{\textcircled{6}} = \frac{2}{3} \\ \begin{array}{r} 3) \cdot 784 \\ \hline .261\text{\textcircled{8}} \end{array} \qquad \begin{array}{r} 2 \\ 3)1 \cdot 7522 \\ \hline .5840\text{\textcircled{8}} \end{array} \end{array}$$

As the denominator of the vulgar fractions always consists of 8's or of 9's with ciphers annexed, we may use the contraction explained p. 549, col. 1, par 1, &c.; and this will lead us exactly to the same operation which was explained p. 564, col. 1, par. 1, &c. on the principles of decimal arithmetic.

$$\begin{array}{r} 7th, .735 \times .326 = \frac{323}{990} \qquad 8th, .278 \times .365 = \frac{365}{990} \\ \begin{array}{r} 323 \\ 2205 \\ 1470 \\ 2205 \\ \hline 99)237405 \\ 2374,05 \\ 23,74 \\ ,23 \\ \hline .239803, \end{array} \qquad \begin{array}{r} 365 \\ 1390 \\ 1668 \\ 834 \\ \hline 999)101470, \\ 101, \\ \hline .101,571, \end{array} \end{array}$$

When the multiplier is a mixed repeater or circulate, we may proceed as in *Ex. 4th* and *7th*; or we may divide the

multiplier into two parts, of which the first is finite, and the second a pure repeater or circulate, with ciphers prefixed, and multiply separately by these, and add the products.

$$\begin{array}{r} \text{Thus, } .384 \times .2\text{\textcircled{8}} \text{ or by } .2 = .0768 \text{ or thus, } .384 \\ \text{and by } .05 = .0213\text{\textcircled{8}} \\ \hline .09813 \qquad 9)1920 \\ \hline 213\text{\textcircled{8}} \\ 768 \\ \hline .0981\text{\textcircled{8}} \end{array}$$

In the following examples the multiplicand is a repeater, and therefore the multiplication by the numerator of the vulgar fraction is performed as directed p. 564, col. 1.

$$\begin{array}{r} 9th, .68\text{\textcircled{8}} \times \text{\textcircled{5}} = \frac{5}{9} \qquad 10th, .6\text{\textcircled{8}} \times .2,39 = \frac{237}{990} \\ \begin{array}{r} 5 \\ 9)3-41\text{\textcircled{8}}(.37,962, \\ 27 \\ \hline 71 \\ 63 \\ \hline *86 \\ 81 \\ \hline 56 \\ 54 \\ \hline 26 \\ 18 \\ \hline *86 \end{array} \qquad \begin{array}{r} .237 \\ 2 \\ \hline 443 \\ 189\text{\textcircled{8}} \\ \hline 1266\text{\textcircled{8}} \\ 99)15010(.15,16, \\ 99 \\ \hline 511 \\ 495 \\ \hline *160 \\ 99 \\ \hline 610 \\ 594 \\ \hline *16 \end{array} \end{array}$$

In the following examples the multiplicand is a circulate, and therefore the multiplication by the numerator is performed as directed, p. 563, col. 2, par *ult.*

$$\begin{array}{r} 11th, .3,81 \times .5\text{\textcircled{8}} = \frac{48}{90} \\ \begin{array}{r} 48 \\ 3054 \\ 15272 \\ \hline 9)0)183,27, (.203,63, \\ 18 \\ \hline *032 \\ 27 \\ \hline 57 \\ 54 \\ \hline *32 \end{array} \qquad 12th, .12 \times .03 = \frac{3}{9} \\ \begin{array}{r} 3 \\ 99)36,36(.036730945821854912764, \\ 666 \\ 723 \\ 306 \\ 936 \\ 453 \\ 576 \\ 813 \\ 216 \\ 183 \\ 846 \\ 543 \\ 486 \\ 903 \\ 126 \\ 273 \\ 756 \\ 633 \\ 396 \\ \hline *036 \end{array} \end{array}$$

In *Ex. 12* we have omitted the products of the divisor, and only marked down the remainders. These are found

Decimal Fractions. by adding the left-hand figure of the dividual to the remaining figures of the same. Thus, 363 is the first dividual, and 3, the left hand figure, added to 63, the remaining figures, gives 66 for the first remainder; and the second dividual, 666, is completed by annexing the circulating figure 6, the reason of which may be explained as follows. The highest place of each dividual shows, in this example, how many hundreds it contains; and as it must contain an equal number of ninety-nines, and also an equal number of units, it follows that these units, added to the lower places, must show how far the dividual exceeds that number of ninety-nines. The figure of the quotient is generally the same as the first place of the dividual, sometimes one more. This happens in the last step of the foregoing example, and is discovered when the remainder found, as here directed, would amount to 99 or upwards; and the excess above 99 only must in that case be taken to complete the next dividual.

$$14th, \cdot 01, \times \cdot 01, = \frac{1}{99}$$

99)01(·000102030405060708091011121314151617181920
 (2122232425262728293031323334353637383940
 (4142434445464748495051525354555657585960
 (6162636465666768697071727374757677787980
 (81828384858687888990919293949596979899

The number of places in the circle of the product is sometimes very great, though there be few places in the factors; but it never exceeds the product of the denominator of the multiplier, multiplied by the number of places in the circle of the multiplicand. Therefore, if the multiplier be $\frac{1}{9}$ or $\frac{1}{8}$, the product may circulate three times as many places as the multiplicand; if the multiplier be any other repeater, nine times as many; if the multiplier be a circulate of two places, ninety-nine times as many: thus, in the last example, $\cdot 01$, a circulate of two places, multiplied by $\cdot 01$, a circulate of two places, produces a circulate of twice 99, or 198 places. And the reason of this limit may be inferred from the nature of the operation; for the greatest possible number of remainders, including 0, is equal to the divisor 99; and each remainder may afford two dividuals, if both the circulating figures, 3 and 6, occur to be annexed to it. If the multiplier circulate three places, the circle of the product, for a like reason, may extend 999 times as far as that of the multiplicand. But the number of places is often much less.

SECT. IV.—DIVISION OF INTERMINATE DECIMALS.

CASE I.—When the dividend only is interminate, proceed as in common arithmetic; but when the figures of the dividend are exhausted, annex the repeating figure, or the circulating figures in their order, instead of ciphers, to the remainder.

Ex. 1st, Divide $\cdot 5326$ by $\cdot 7$ 2d, Divide $\cdot 84\frac{1}{2}$ by 5.

$$\begin{array}{r} \cdot 1) \cdot 5326 (\cdot 76,095238, \\ 49 \\ \hline 42 \\ 42 \\ \hline *066 \\ 63 \\ \hline 36 \\ 35 \\ \hline 16 \\ 14 \\ \hline 26 \\ 21 \\ \hline 56 \\ 56 \\ \hline *066 \end{array}$$

$$\begin{array}{r} 5) \cdot 84\frac{1}{2} (\cdot 168\frac{1}{2} \\ 5 \\ \hline 34 \\ 30 \\ \hline 43 \\ 40 \\ \hline *33 \\ 30 \\ \hline *33 \end{array}$$

3d, Divide $\cdot 6532\frac{1}{2}$ by 8.
 8) $\cdot 6532\frac{1}{2}$ ($\cdot 08166\frac{1}{2}$.

Decimal Fractions. In these accounts the quotient is never finite. It may repeat if the dividend repeat; or, if the dividend circulate, it may circulate an equal number of places, often more, and never fewer. The greatest possible extent of the circle is found by multiplying the divisor into the number of places in the circle of the dividend. Thus, a circulate of 3 places, divided by 3, quotes a circulate of 3 times 3 or 9 places.

CASE II.—When the divisor is interminate, the multiplications and subtractions must be performed according to the directions given for repeating and circulating decimals.

Ex. 1st, Divide $\cdot 37845$ by $\frac{1}{5}$.

$$\begin{array}{r} 5) \cdot 37845 (\cdot 68121 \\ 33333\frac{1}{2} \\ \hline 4511\frac{1}{2} \\ 4444\frac{1}{2} \\ \hline 67\frac{1}{2} \\ 55\frac{1}{2} \\ \hline 11\frac{1}{2} \\ 11 \\ \hline 0 \end{array}$$

2d, Divide $\cdot 245892$ by $2 \cdot 18$

$$\begin{array}{r} 2 \cdot 18) \cdot 245892 (1 \cdot 127005 \\ 218181,81, \\ \hline 27710,18, \\ 21818,18, \\ \hline 5892,00, \\ 4363,63, \\ \hline 1528,36, \\ 1527,2\frac{1}{2}, \\ \hline 1090,90 \\ 1090,90 \\ \hline 0 \end{array}$$

The foregoing method is the only one which properly depends on the principles of decimal arithmetic; but it is generally shorter to proceed by the following rule.

Reduce the divisor to a vulgar fraction, multiply the dividend by the denominator, and divide the product by the numerator.

Ex. 1st, Divide $\cdot 37845$ by $\frac{1}{5} = \frac{5}{5}$.

$$5)3 \cdot 40605 (\cdot 68121.$$

2d, Divide $\cdot 3784\frac{1}{2}$ by $\frac{2}{3}$

$$2)1 \cdot 1353\frac{1}{2} (\cdot 56768\frac{1}{2}.$$

Note 1. Division by $\frac{1}{3}$ triples the dividend, and division by $\frac{1}{2}$ increases the dividend one half.

Note 2. When the divisor circulates, the denominator of the vulgar fraction consists of 9's, and the multiplication is sooner performed by the contraction explained p.546, col. 1. It may be wrought in the same way when the divisor repeats, and the denominator of consequence is 9.

Note 3. If a repeating dividend be divided by a repeating or circulating divisor; or, if a circulating dividend be divided by a similar circulating divisor; or, if the number of places in the circle of the divisor be a multiple of the number in the dividend; then the product of the dividend multiplied by the denominator of the divisor will be terminate, since like figures are subtracted from like in the contracted multiplication, and consequently no remainder left.

Note 4. In other cases the original and multiplied dividend are similar, and the form of the quotient is the same as in the case of a finite divisor.

Decimal
Fractions.

Note 5. If the terms be similar, or extended till they become so, the quotient is the same as if they were finite, and the operation may be conducted accordingly; for the quotient of vulgar fractions that have the same denominator is equal to the quotient of their numerators.

you may continue the operation by annexing periods, or pairs of ciphers, till there be no remainder, or till the decimal part of the quot repeat or circulate, or till you think proper to limit it.

Ex. 1st, Required the square root of 133225.

Square number	133225(365 root.	365
	9	365
1 div. 66)	432 resolvend.	1825

After getting half of the decimal places, work by contracted division for the other half; and obtain them with the same accuracy as if the work had been at large.

3d, Required the square root of .2916.

.2916(.54 root.	
25	
104)416	
416	

If the square root of a vulgar fraction be required, find the root of the given numerator for a new numerator, and find the root of the given denominator for a new denominator. Thus the square root of $\frac{4}{9}$ is $\frac{2}{3}$, and the root of $\frac{16}{25}$ is $\frac{4}{5}$; and thus the root of $\frac{49}{4}$ ($= 6\frac{1}{4}$) is $\frac{7}{2} = 3\frac{1}{2}$.

But if the root of either the numerator or denominator cannot be extracted without a remainder, reduce the vulgar fraction to a decimal, and then extract the root, as in Ex. 3d, above.

CHAP. XI.—OF THE EXTRACTION OF ROOTS.

The origin of powers of involution has already been explained under the article ALGEBRA. There now remains, therefore, only to give the most expeditious methods of extracting the square and cube roots; the reasons of which will readily appear from what is said under that article. As for all powers above the cube, unless such as are multiples of either the square or cube, the extraction of their roots admits of no deviation from the algebraic canon, which must be always constructed on purpose for them.

If the root of any power not exceeding the seventh power be a single digit, it may be obtained by inspection from the following Table of powers.

1st power or root.	2d power or square.	3d power or cube.	4th power or biquadrate.	5th power or sursolid.	6th power or cube squared.	7th power.
1	1	1	1	1	1	1
2	4	8	16	32	64	128

9	81	729	6561	59049	531441	4782969

SECT. I.—EXTRACTION OF THE SQUARE ROOT.

RULE I.—Divide the given number into periods of two figures, beginning at the right hand in integers, and pointing toward the left. But in decimals begin at the place of hundreds; and point toward the right. Every period will give one figure in the root.

II.—Find by the table of powers, or by trial, the nearest lesser root of the left-hand period; place the figure so found in the quot; subtract its square from the said period, and to the remainder bring down the next period for a dividial or resolvend.

III.—Double the quot for the first part of the divisor; inquire how often this first part is contained in the whole resolvend, excluding the unit's place; and place the figure denoting the answer both in the quot and on the right of the first part; and you have the divisor complete.

IV.—Multiply the divisor, thus completed, by the figure put in the quot, subtract the product from the resolvend, and to the remainder bring down the following period for a new resolvend, and then proceed as before.

Note 1st, If the first part of the divisor, with unity supposed to be annexed to it, happen to be greater than the resolvend, in this case place 0 in the quot, and also on the right of the partial divisor; to the resolvend bring down another period; and proceed to divide as before.

Note 2d, If the product of the quotient figure into the divisor happen to be greater than the resolvend, you must go back and give a lesser figure to the quot.

Note 3d, If, after every period of the given number is brought down, there happen at last to be a remainder,

SECT. II.—EXTRACTION OF THE CUBE ROOT.

RULE I.—Divide the given number into periods of three figures, beginning at the right hand in integers, and pointing toward the left. But in decimals, begin at the place of thousands, and point toward the right. The number of periods shows the number of figures in the root.

II.—Find by the table of powers, or by trial, the nearest lesser root of the left-hand period; place the figure so found in the quot; subtract its cube from the said period; and to the remainder bring down the next period for a dividial or resolvend.

The divisor consists of three parts, which may be found as follows:

Ans. III. The first part of the divisor is found thus: Multiply the square of the quot by 3, and to the product annex two ciphers; then inquire how often this first part of the divisor is contained in the resolvend, and place the figure denoting the answer in the quot.

IV. Multiply the former quot by 3, and the product by the figure now put in the quot; to this last product annex a cipher, and you have the second part of the divisor. Again, square the figure now put in the quot for the third part of the divisor; place these three parts under one another as in addition, and their sum will be the divisor complete.

V. Multiply the divisor thus completed by the figure last put in the quot, subtract the product from the resolvend, and to the remainder bring down the following period for a new resolvend, and then proceed as before.

Note 1. If the first part of the divisor happen to be equal to or greater than the resolvend, in this case place 0 in the quot, annex two ciphers to the said first part of the divisor, to the resolvend bring down another period, and proceed to divide as before.

Note 2. If the product of the quotient figure into the divisor happen to be greater than the resolvend, you must go back, and give a lesser figure to the quot.

Note 3. If, after every period of the given number is brought down, there happen at last to be a remainder, you may continue the operation by annexing periods of three ciphers till there be no remainder, or till you have as many decimal places in the root as you judge necessary.

Ex. 1st, Required the cube root of 12812904.

Cube number 12812904 (234 root.

97384 rem.

28.750000 cube.

If the cube root of a vulgar fraction be required, find the cube root of the given numerator for a new numerator, and the cube root of the given denominator for a new denominator. But if the root of either cannot be extracted without a remainder, reduce the vulgar fraction to a decimal, and then extract the root.

ARIUS, a divine of the fourth century, the head and founder of the Arians, a sect which denied the eternal divinity and substantiality of the Word, was born in Libya. Eusebius, bishop of Nicomedia, a great favourite of Constantia, sister of the emperor Constantine, and wife of Licinius, became a zealous promoter of Arianism. He took Arius under his protection, and introduced him to Constantia; so that the sect increased, and several bishops embraced it openly. In the cities, however, disputes arose so high, that the emperor was obliged to assemble a council—that of Nice—where, in the year 325, the doctrine of Arius was condemned, he himself banished by the emperor, all his books ordered to be burnt, and capital punishment denounced against whoever dared to keep them. After five years' banishment, he was recalled to Constantinople, where he presented the emperor with a confession of his faith, drawn up so artfully, that it fully satisfied him. Notwithstanding which, Athanasius, now advanced to the see of Alexandria, refused to admit him and his followers to communion. This so enraged them, that by their interest at court they procured the deposition and banishment of that prelate. But the church of Alexandria still refusing to admit Arius into their communion, the emperor sent for him to Constantinople, where, upon delivering in a fresh confession of his faith in terms less offensive, the emperor commanded Alexander, the bishop of that church, to receive him the next day into his communion; but that very evening Arius died suddenly. The heresy, however, did not ex-

pire with the heresiarch: his party continued still in great credit at court. Athanasius, indeed, was soon recalled from banishment, but as soon removed again; for the Arians, under the countenance of government, made and deposed bishops as it best served their purposes. In short, this sect shone with great lustre above 300 years. It was the reigning religion of Spain for above two centuries; it was on the throne both in the East and West; it prevailed in Italy, France, Pannonia, and Africa; and was not extirpated till about the end of the 8th century. It was afterwards set on foot in the West by Servetus. Erasmus seems to have aimed at reviving it in his Commentaries on the New Testament; and the learned Gro-tius appears to favour the doctrine.

ARK, NOAH'S, a floating vessel built by Noah, for the preservation of his family, and the several species of animals, during the deluge. The ark has afforded several points of curious inquiry relating to its form, capacity, materials, &c. The wood of which it was built is called in the Hebrew *gopher wood*, and in the Septuagint *square timbers*. Some translate the original *cedar*, others *pine*, others *box*, &c. Pelletier prefers cedar, on account of its incorruptibility and the great plenty of it in Asia. Fuller and Bochart contend that it was built of what the Greeks call *καταγισσος*, or the *cypress tree*; for, taking away the termination, *kupar* and *gopher* differ very little in sound. In what place Noah built and finished his ark is no less a matter of disputation; but the most general opinion is, that it was built in Chaldea, in the territories

Arklow
||
Arkwright.

of Babylon. Its dimensions, as given by Moses, are 300 cubits in length, 50 in breadth, and 30 in height; which some have thought too scanty, considering the number of things it was to contain; and hence an argument has been drawn against the authority of the relation. But Buteo and Kircher have shown geometrically, that, taking the common cubit of a foot and a half, the ark was sufficient for all the animals supposed to be lodged in it. Father Lamy contends that it was 110 feet longer than the church of St Mary at Paris, and 64 feet narrower; and Dr Arbuthnot computes it to have been 81,062 tons. It contained, besides eight persons of Noah's family, one pair of every species of unclean animals, and seven pair of every species of clean animals, with provisions for them all during the whole year. By the description Moses gives of the ark, it appears to have been divided into three stories, each ten cubits or 15 feet high; and it is agreed on, as most probable, that the lowest story was for the beasts, the middle for the food, and the upper for the birds, with Noah and his family.

ARK of the Covenant, a small chest or coffer, three feet nine inches in length, two feet three inches in breadth, and two feet three inches in height, in which were contained the golden pot that held manna, and Aaron's rod, and the tables of the covenant. This coffer was made of shittim-wood, and covered with a lid, which was made of solid gold. The ark was repositied in the holiest place of the tabernacle. It was taken by the Philistines, and detained 20, some say 40 years, at Kirjath-jearim; but the people being afflicted with emerods on account of it, returned it with divers presents. It was afterwards placed in the temple. The lid or covering of the ark was called the *propitiatory* or *mercy-seat*; over which were two figures placed called *cherubims*, with expanded wings of a peculiar form. Here the Schechinah rested both in the tabernacle and temple in a visible cloud, hence were issued the Divine oracles by an audible voice; and the high priest appeared before this mercy-seat once every year, on the great day of expiation; and the Jews, wherever they worshipped, turned their faces towards the place where the ark stood. In the second temple there was also an ark, made of the same shape and dimensions with the first, and put in the same place, but without any of its contents and peculiar honours. It was used as a representative of the former on the day of expiation, and as a repository of the original copy of the Holy Scriptures, collected by Ezra and the men of the great synagogue, after the captivity.

ARKLOW, a seaport town of Ireland, in the county of Wicklow, situated on the south side of the river Avoca or Ovoca, near the Irish Sea. The river is crossed by a bridge of 19 arches, and its harbour admits small vessels. It contains a charter-school for 50 girls; and there are barracks at its western extremity. It was assailed in 1798 by a body of insurgents, and suffered considerable damage, though they were finally dispersed. Population 3808. 17 miles S. from Wicklow, and 49 S. E. from Dublin. Long. 6. 0. W. Lat. 52. 48. N.

ARKWRIGHT, SIR RICHARD, famous for his inventions in cotton spinning, was born at Preston in Lancashire, in 1732, of parents in humble circumstances. He was the youngest of thirteen children, received but a very indifferent education, and was bred to the trade of a barber. But the *res angusta domi* could not repress the native vigour of his mind, or extinguish the desire he felt to emerge from his low situation. In the year 1760 he

had established himself in Bolton-le-Moor, where he exchanged the trade of a barber for that of an itinerant hair-merchant; and having discovered a valuable chemical process for dying hair, he was in consequence enabled to amass a little property. It is unfortunate that very little is known of the steps by which he was led to those inventions that raised him to distinction, and have immortalized his name. His residence in a district where a considerable manufacture of linen goods, and of linen and cotton mixed, was carried on, must have given him ample opportunities of becoming acquainted with the various processes that were in use in the cotton manufacture, and of the attempts that had been made and were then making to improve them. His attention was thus naturally drawn to this peculiar department; and, while he saw reason to conclude that it was likely to prove the most advantageous in which he could engage, he had sagacity and good fortune to invent and improve those extraordinary machines by which, unlike most inventors, he amassed vast wealth, at the same time that he added prodigiously to the demand for labour, and to the riches and comfort of the civilized world.

The *spinning-jenny*, invented in 1767 by Hargraves, a carpenter at Blackburn in Lancashire, gave the means of spinning twenty or thirty threads at once with no more labour than had previously been required to spin a single thread. The thread spun by the jenny could not, however, be used, except as weft, being destitute of the firmness or hardness required in the longitudinal threads or warp. But Mr Arkwright supplied this deficiency by the invention of the *spinning-frame*—that wonderful piece of machinery, which spins a vast number of threads of any degree of fineness and hardness, leaving to man merely to feed the machine with cotton, and to join the threads when they happen to break. It is not difficult to understand the principle on which this machine is constructed, and the mode of its operation. It consists of two pairs of rollers, turned by means of machinery. The lower roller of each pair is furrowed or fluted longitudinally, and the upper one is covered with leather, to make them take a hold of the cotton. If there were only one pair of rollers, it is clear that a carding of cotton, passed between them, would be drawn forward by the revolution of the rollers; but it would merely undergo a certain degree of compression from their action. No sooner, however, has the carding, or *roving* as it is technically termed, begun to pass through the first pair of rollers, than it is received by the second pair, which are made to revolve with (as the case may be) three, four, or five times the velocity of the first pair. By this admirable contrivance, the roving is drawn out into a thread of the desired degree of tenuity, a twist being given to it by the adaptation of the spindle and fly of the common flax wheel to the machinery.

Such is the principle on which Mr Arkwright constructed his famous spinning-frame. It is obvious that it is radically different from the previous methods of spinning either by the common hand-wheel or distaff, or by the jenny, which is only a modification of the common wheel. Spinning by rollers was an entirely original idea; and it is difficult to determine which is most worthy of admiration—the genius which led to so great a discovery, or the consummate skill and address by which it was so speedily perfected and reduced to practice. Mr Arkwright stated that he accidentally derived the first hint of his great invention from seeing a red-hot iron bar elongated by being made to pass between rollers;¹ and though

¹ See the account of Mr Arkwright, in the article Derbyshire, in the *Beauties of England and Wales*, vol. iii. p. 518. The statements in this account are of the highest authority, inasmuch as we have reason to believe it was furnished by Mr Strutt, the son of Mr Arkwright's first partner.

there is no mechanical analogy between that operation and his process of spinning, it is not difficult to imagine, that by reflecting upon it, and placing the subject in different points of view, it might lead him to his invention. The precise era of the discovery is not known; but it is most probable that the felicitous idea of spinning by rollers had occurred to his mind as early as the period when Hargraves was engaged in the invention of the jenny, or almost immediately after. Not being himself a practical mechanic, Arkwright employed a person of the name of John Kay, a watchmaker at Warrington, to whom we shall afterwards have to refer, to assist him in the preparation of the parts of his machine. Having made some progress towards the completion of his inventions, he applied in 1767 to Mr Atherton of Liverpool for pecuniary assistance to enable him to carry them into effect; but this gentleman declined embarking his property in what appeared so hazardous a speculation, though he is said to have sent him some workmen to assist in the construction of his machine; the first model of which was set up in the parlour of the house belonging to the free grammar school at Preston.

His inventions being at length brought into a pretty advanced state, Arkwright, accompanied by Kay, and a Mr Smalley of Preston, removed to Nottingham in 1768, in order to avoid the attacks of the same lawless rabble that had driven Hargraves out of Lancashire. Here his operations were at first greatly fettered by a want of capital. But Mr Strutt¹ of Derby, a gentleman of great mechanical skill, and largely engaged in the stocking manufacture, having seen Arkwright's inventions, and satisfied himself of their extraordinary value, immediately entered, conjointly with his partner Mr Need, into partnership with him. The command of the necessary funds being thus obtained, Mr Arkwright erected his first mill, which was driven by horses, at Nottingham, and took out a patent for spinning by rollers, in 1769. But as the mode of working the machinery by horse-power was found too expensive, he built a second factory, on a much larger scale, at Cromford in Derbyshire, in 1771, the machinery of which was turned by a water-wheel, after the manner of the famous silk-mill erected by Sir Thomas Lombe. Having made several additional discoveries and improvements in the processes of carding, roving, and spinning, he took out a fresh patent for the whole in 1775; and thus completed a series of machinery so various and complicated, yet so admirably combined, and well adapted to produce the intended effect, in its most perfect form, as to excite the astonishment and admiration of every one capable of appreciating the ingenuity displayed and the difficulties overcome.²

When the vast importance of these discoveries became known, it is not surprising that every effort should have been made to have the patents set aside, and Mr Arkwright deprived of the profit and honour to be derived from them. But after a pretty attentive consideration of the various proceedings relative to this subject, we have no hesitation in saying, that we see no good grounds for crediting the statement made in the court of king's bench

in 1785, and recently repeated by Mr Guest in his work on the cotton manufacture, which ascribes the invention of spinning by rollers to Highs or Hayes, from whom Arkwright is said to have learned it; and we shall now briefly state our reasons for holding this opinion.

Mr Arkwright's *first* patent for spinning by rollers, which is by far the most important, or rather, indeed, the essential part of his inventions, was obtained, as we have previously stated, in 1769; and its value and importance were no longer doubtful after the establishment of the factory at Cromford in 1771. The success which attended this novel method of spinning naturally excited the strongest desire on the part of the Lancashire manufacturers to participate in the advantages to be derived from it; and the fair presumption is, that instead of attempting clandestinely to pirate the invention, they would, had they conceived there were any good grounds to go upon, have at once contested the validity of the patent. But no such attempt was made till 1781, *twelve* years after the date of the first patent, and *six* years after the date of the second. And, even at that late period, Mr Arkwright's opponents came forward only in consequence of his having resolved to vindicate his rights, which had begun to be invaded on all sides, by raising an action against Colonel Mordaunt for an infringement of his patent. Mordaunt was supported by a combination of manufacturers; and, as they felt the question to be of the greatest importance, it is all but impossible to suppose that any thing would be omitted on their part which was conceived likely to contribute to their success. The case having been tried in the court of king's bench, after Trinity term, July 1781, the decision was unfavourable to Mr Arkwright. But it is of importance to observe, that no attempt was made at the trial to charge him with having purloined the inventions of others, and that the verdict was given on the sole ground of the *description of the machinery in the specification being obscure and indistinct*. Mr Arkwright admitted that such was partly the case; adding, however, that the obscurity charged against the specification had been intended only to prevent foreigners from pirating his inventions. On any other principle, indeed, his conduct would be inexplicable; for, as his inventions were fully known to hundreds of workmen in his own employment, and as he had sold the privilege of using them to great numbers of individuals in different parts of the country, it is impossible to suppose that he could either have expected or intended to conceal his inventions after the expiration of his patent.³ In consequence of the result of this trial, Mr Arkwright and his partners prepared a *Case*, setting forth the value of the inventions, and the circumstances which had led to the indistinctness complained of in the specification, which they at one time intended to lay before parliament, as the foundation of an application for an act for their relief. But this intention was subsequently abandoned; and in a new trial (*Arkwright v. Nightingale*), which took place in the court of common pleas on the 17th of February 1785, Lord Loughborough, the presiding judge, having expressed himself favourably with respect to the sufficiency

¹ This was the justly celebrated Mr Jedediah Strutt. He was the son of a farmer, and was born in 1726. His father paid little attention to his education; but, under every disadvantage, he acquired an extensive knowledge of science and literature. He was the first individual who succeeded in adapting the stocking-frame to the manufacture of *ribbed* stockings. The manufacture of these stockings, which he established at Derby, was conducted on a very large scale, first by himself and his partner Mr Need, and subsequently by his sons, until about 1805, when they withdrew from this branch of business.

² See the *Case of Richard Arkwright & Co. in 1782*; the account of Sir Richard Arkwright in Aikin's *Biographical Dictionary*; the *History, Gazetteer, &c. of Lancashire*, by Edward Baines, vol. ii. p. 484, &c.

³ It was erroneously stated, in an article in the *Edinburgh Review* (No. 91), from which this sketch is principally abstracted, on the authority of the article "Cotton Manufacture," in the Supplement to this work. (vol. iii. p. 394), that a trial had been instituted in 1772, in which Mr Arkwright proved successful, to have the original patent set aside. But the first trial did not really take place, as above stated, till 1781.

Arkwright of the specification, a verdict was given for Mr Arkwright. On this, as on the former trial, nothing was stated against the originality of the invention.

In consequence of these conflicting verdicts, the whole matter was brought, by a writ of *scire facias*, before the court of king's bench, to have the validity of the patent finally settled. And it was not till this third trial, which took place before Mr Justice Buller and a special jury, on the 25th of June 1785, that Mr Arkwright's claim to the inventions which formed the subject of the patent was disputed. To support this new allegation, Mr Arkwright's opponents brought forward, for the first time, Highs or Hayes, a reed-maker at Bolton. He stated that he had invented a machine for spinning by rollers previously to 1768; that he had employed the watchmaker Kay, to whom we have already referred, to make a model of that machine; and Kay was produced to prove that he had communicated that model to Mr Arkwright, and that that was the real source of all his pretended inventions. Having no idea that any attempt was to be made at so late a period to overturn the patent on this new ground, Mr Arkwright's counsel were not prepared with evidence to repel this statement; but it was stated by Mr Sergeant Adair, on a motion for a new trial on the 10th of November of the same year, that he was furnished with affidavits contradicting, in the most pointed manner, the evidence that had been given by Kay and others with respect to the originality of the invention. The court, however, refused to grant a new trial, on the ground, that whatever might be the fact as to the question of originality, the deficiency in the specification was enough to sustain the verdict.

But, independently altogether of the statements made on the motion for a new trial, the improbability of the story told by Highs and Kay seems glaring and obvious. Highs states in his evidence that he had accused Arkwright of getting possession of his invention by means of Kay so early as 1769, or about that period. Where, then, it may be asked, was this Mr Highs ever since that period, and particularly during the first trial in July 1781, and the second in February 1785? Living in Lancashire, associating with manufacturers, and in the habit, as he declares in his evidence, of making machines for them, he could not fail to be speedily informed with respect to the vast importance and value of the invention Mr Arkwright had purloined from him. It is impossible but he must have been acquainted with the efforts that were making by the Lancashire manufacturers to set aside the patents; and is it to be supposed, had he really been the inventor, that he would have remained for *sixteen* years a passive spectator of what was going forward? that he would have allowed Mr Arkwright to accumulate a princely fortune by means of *his* inventions, while he remained in a state of poverty? or that he would have withheld his evidence when the manufacturers attempted to wrest from Mr Arkwright what he had so unjustly appropriated? A single hint from Highs or Kay would, had their story been well founded, have sufficed to force Mr Arkwright to give them a share of his profits, or would have furnished the manufacturers with the means they were so anxious to obtain, of procuring the immediate dissolution of the patents. But it has never been alleged that Mr Arkwright took any pains to conciliate these persons: on the contrary, he treated Highs with the most perfect indifference, and not only dismissed Kay from his service, but even threatened to prosecute him on a charge of felony. And can any one imagine for a moment, that persons with so many and such overpowering temptations

to speak out, and with no inducement of any sort to be silent, should have gone about for more than twice the period of a Pythagorean noviciate, with so important a secret closely pent up in their bosoms? We confess that such a supposition seems to us altogether absurd and incredible; and we believe our readers will agree with us in thinking, that it is infinitely more consistent with probability to suppose that the story of Highs and Kay had been manufactured for the occasion, than that it was really true.

The improbability of the statements made on this subject by Guest, in his *History of the Cotton Manufacture*, appear still more obvious, from his attributing to Highs the invention, not only of the spinning frame, but also of the jenny, which had been universally ascribed to Hargraves. But no weight can be attached to such rash and ill-considered statements. It would be next to a miracle, had two methods of spinning, both very ingenious, but radically different in their first principles, been invented nearly at the same time by the same individual.

It appears, from a communication from Mr Charles Wyatt to his brother, in the *Repertory of Arts* for 1817, and which has been reprinted by Mr Kennedy, in an interesting article on the Rise and Progress of the Cotton Trade, in the *Manchester Memoirs* (2d series, vol. iii. p. 135), as well as from the distinct reference to them in the *Case* printed by Mr Arkwright in 1782, that attempts had been made in the early part of last century to spin cotton by means of machinery. But these attempts proved ruinous to the parties by whom they were made; and all knowledge of the machinery by which they attempted to effect their purpose has been long since lost. Mr Kennedy says he had seen a specimen of yarn spun about 1741, by the late Mr Wyatt of Birmingham; but he expresses his opinion that no competent judge would say that it was spun by a similar machine to that of Mr Arkwright. It was not indeed alleged at any of the trials that took place with respect to the validity of his patent, nor has it ever been alleged since, that he had borrowed anything whatever from these remote attempts. If he was really indebted to them, it must have been merely for the knowledge of the fact that such attempts had been made; and this might have stimulated him to turn his attention to the subject.

We have access to know that none of Mr Arkwright's most intimate friends, and who were best acquainted with his character, ever had the slightest doubt with respect to the originality of his invention. Some of them, indeed, could speak to the circumstances from their own personal knowledge; and their testimony was uniform and consistent. Such also seems to be the opinion now generally entertained among the principal manufacturers of Manchester. In proof of this, we may again refer to Mr Kennedy's valuable paper in the *Manchester Memoirs*. Mr Kennedy is one of the most eminent and intelligent cotton manufacturers in the empire, and it is of importance to remark, that, although he was resident in Manchester in 1785, when the last trial for setting aside Mr Arkwright's patent took place, and must, therefore, have been well acquainted with all the circumstances connected with it, he does not insinuate the smallest doubt as to his being the real inventor of the spinning frame, nor even so much as once alludes to Highs.

On their first introduction, Mr Arkwright's machines were reckoned by the lower classes as even more adverse to their interests than those of Hargraves; and reiterated attacks were made on the factories built for them.¹ But

¹ Dornier Rasbotham, Esq. a magistrate near Bolton, printed, some time about the period referred to, a sensible address to the weavers and spinners, in which he endeavoured to convince them that it was for their interest to encourage inventions for abridging

Arkwright. how extraordinary soever it may appear, it was amongst the manufacturers that the greatest animosity existed against Mr Arkwright; and it required all the prudence for which he was so remarkable to enable him to triumph over the powerful combination that was formed against him. At the outset of the business, they unanimously refused to purchase his yarn; and when his partners, Messrs Strutt and Need, had commenced a manufacture of calicoes, the manufacturers strenuously opposed a bill to exempt calicoes from a discriminating duty of 3d a yard laid on them, over and above the ordinary duty of 3d by an old act of parliament. Luckily, however, the manufacturers failed of their object; and, in 1774, an act of parliament was obtained (14th Geo. III. cap. 72), for the encouragement of the cotton manufacture, in which fabrics made of cotton are declared to have been *lately* introduced, and are allowed to be used as "a lawful and laudable manufacture;" the duty of 6d the square yard on such cottons as are printed or stained being at the same time reduced to 3d. But this disgraceful spirit of animosity, which must, had it been successful, have proved as injurious to the interests of the manufacturers as to those of Mr Arkwright, did not content itself with actions in the courts of law, or a factious opposition to useful measures in parliament, but displayed itself in a still more striking and unjustifiable manner; for it is a fact, that a large factory, erected by Mr Arkwright at Birkacre, near Chorley, in Lancashire, was destroyed by a mob collected from the adjacent country, in the presence of a powerful body of police and military, without any one of the civil authorities requiring them to interfere to prevent so scandalous an outrage.

Fortunately, however, not for himself only, but for his country and the world, every corner of which has been benefited by his inventions, Mr Arkwright triumphed over every opposition. The same ingenuity, skill, and good sense, which had originally enabled him to invent his machine and get it introduced, enabled him to overcome the various combinations and difficulties with which he had subsequently to contend.

Though a man of great personal strength, which he is said to have displayed when young, in election riots at Preston, Mr Arkwright never enjoyed good health. During the whole of his splendid and ever memorable career of invention and discovery, he was labouring under a very severe asthmatic affection. A complication of disorders at length terminated his truly useful life in 1792, at his works at Cromford, in the sixtieth year of his age. He was high sheriff of Derbyshire in 1786; and, having presented a congratulatory address from the wapentake of Wirksworth to his majesty George III., on his escape from the attempt on his life by Margaret Nicholson, received the honour of knighthood. No man ever better deserved his good fortune, or has a stronger claim on the respect and gratitude of posterity. His inventions have opened a new and boundless field of employment; and while they have conferred infinitely more real benefit on his native country than she could have derived from the absolute dominion of Mexico and Peru, they have been *universally* productive of wealth and enjoyments.

"The originality and comprehensiveness of Sir Richard Arkwright's mind," says Mr Bannatyne, "was perhaps marked by nothing more strongly than the judgment with

which, although new to business, he conducted the great concerns his discovery gave rise to, and the systematic order and arrangement which he introduced into every department of his extensive works. His plans of management, which must have been entirely his own, as no establishment of a similar nature then existed, were universally adopted by others; and, after long experience, they have not yet, in any material point, been altered or improved."

Mr Arkwright was twice married. By his first marriage he had a son, the present Richard Arkwright, Esq. of Willersley Castle, near Cromford; by his second marriage he had a daughter, now Mrs Charles Hurt of Wirksworth, Derbyshire. Both have numerous descendants. (c. c.)

ARLES, an arrondissement in the department of the mouths of the Rhone, in France, extending over 883 square miles, or 585,120 acres. It is divided into eight cantons, and subdivided into 33 communes, which contain 70,641 inhabitants.

ARLES, a city, the chief of the arrondissement of the same name, in France. It is situated on the left bank of the principal branch of the Rhone, called the *Grand Rhone*, to avoid the bad navigation of which, a broad and deep canal to the harbour of Boue has been constructed. The surrounding country is fruitful, especially in corn. The city is ancient, large, and well built, containing, besides a cathedral and several churches, a fine town-house, an exchange, and other public buildings, and 20,151 inhabitants. Having been formerly a Roman colonial city, Arles abounds with many interesting remains of that people. The most remarkable are, an amphitheatre of 1000 feet in circumference, though its arena is filled with miserable dwellings; five arches of Roland's Tower; the remains of the palace of Constantine the Great, called *Le Chateau de Trouille*; the obelisk of granite before the town-house, 61 feet in height; and the Elysian fields, an ancient burial place, with many sarcophagi. It is in long. 5. 42. 27. E. Lat. 43. 40. 28. N.

ARMADA, a Spanish term, signifying a fleet of men of war. The armada which attempted to invade England in the time of Queen Elizabeth is famous in history. See ENGLAND.

ARMADILLO, in *Zoology*. See MAMMALIA *Index*.

ARMAGEDDON, a place spoken of in the Revelation (xvi. 16), which literally signifies the mountain of Mageddon or Megiddo, a city situated in the great plain at the foot of Mount Carmel, where King Josiah received his mortal wound in the battle against Necho, king of Egypt.

ARMAGH, an inland county in the province of Ulster, Boun-
in Ireland, is bounded on the north by Lough Neagh, on daries.
the east by the county of Down, on the south-east by that
of Louth, on the south-west by that of Monaghan, and on
the west by the county of Tyrone. According to Pto-
lemy, it was inhabited by the Vinderii and Voluntii. It
afterwards formed part of a territory called Orgial or Ancient
Uriel, which also extended over Louth, Monaghan, and names.
and some smaller districts. It was likewise subdivided into
the tracts or countries of Clanbrassil, the M'Caahans or
M'Canes, Oirthir or Orior, the O'Hanlons, the Fews, and
Hy Niellan. In the reign of James I. it was made shire
ground, under its present name. It is now divided into Divisions.
the eight baronies of Armagh, Upper Fews, Lower Fews,
O'Neilland East, O'Neilland West, Upper Orior, Lower

labour. The result has shown the soundness of Mr Rasbotham's opinion. It is doubtful whether 30,000 persons were employed in all the branches of the cotton manufacture in 1767; whereas, in consequence of those very inventions which the workmen endeavoured to destroy, there are now upwards of 1,000,000 directly engaged in its different departments! There is, in fact, no idea so groundless and absurd as that which supposes that an increased facility of production can, under any circumstances, be injurious to the labourers.

Armagh. Orior, and Turaney. The superficies of the county has been estimated at 293,919 acres, or nearly 458 square miles.

Extent.

Ecclesiastical arrangements. Considered in its ecclesiastical relations, it forms part of the archiepiscopal province of Armagh, which comprises the dioceses of Armagh, Clogher, Meath, Down, Connor, Derry, Raphoe, Kilmore, Dromore, and Ardagh. The archbishopric of Armagh extends over 468,500 acres, in the counties of Armagh, Londonderry, Tyrone, Louth, and Meath. It contains 111 parishes, consolidated into 80 benefices, having 78 churches, 75 glebe houses, and 16,324 acres of glebe, which, if equally apportioned among the incumbents, would give an average of 204 acres to each. Of these benefices the king presents to 4; the archbishop to 43; other dignitaries of the diocese to 14; laymen to 11; Trinity college, Dublin, to 4; St Patrick's cathedral, Dublin, to one; besides which, there are two joint presentations, and one disputed. The tithe paid by 48 of these parishes, which have conformed to the provisions of the tithe composition act, amounts to L.19,292, being at the rate of L.402 annually to each parish. If the aggregate of the tithe of those which have not yet compounded bear the same proportion to the number of parishes as those which have, the total tithe of the diocese would amount to L.44,613, which, divided among the 80 incumbents, would afford an income to each of L.557 per annum, independently of glebes, manses, or occasional dues. The archbishop's income, derived from lands, is estimated at L.22,000 per annum.

Parishes.

Tithe.

Archbishop's income.

Population.

The county of Armagh contains 22 entire parishes, and 5 parts of parishes, the remainder of which are in some of the adjoining counties. The total population, according to the last census, taken in 1821, amounts to 197,427 souls, being at the rate of one individual to every acre and a half, or one family to every eight acres. Of this population, 28,905 are stated in the same census to be employed in agriculture, 67,182 in trade, manufactures, and commerce, and 14,521 in other occupations, leaving 86,819 of both sexes and of every age unoccupied.

The county of Armagh returns three members to the imperial parliament,—two for the county at large, and one for the city. The election for the county is vested, as in all the other counties of Ireland, in the freeholders, whose number, previously to the passing of the Catholic Relief Bill in 1829, amounted to 8746,—a large number for a county, one of the smallest in superficial extent. These were classed as follows,—203 freeholders holding tenures of L.50 value; 124 of those of L.20; and 8419 of those of L.2, or, as they are more commonly called, forty shilling freeholders. The abolition of the last-named class, which took place at the period just mentioned, reduced the number of electors to 1361, viz. 235 freeholders of L.50; 186 of L.20; and 940 of L.10, which is now the lowest value of a tenure entitling a freeholder to vote.

Soil.

The nature of the soil, and the general character of the land, are well adapted for agricultural purposes. Hills of gentle ascent, of pleasing forms and various altitudes, diversify the surface. Large tracts, particularly in the vicinity of Armagh city, and thence throughout the northern parts, are covered with a stratum of rich productive soil: many of these are well adapted for the culture of wheat, being composed of a strong clay resting on a substratum of excellent limestone. The southern and western parts rise into a rugged, and in many parts a barren elevation, known by the name of the Fews Mountains. The highest of these mountains, and the second in height in the province, is named Slieve-Gallien. Its top is crowned by a large cairn or pile of stones, which forms the roof of a singular cavern of artificial construction, seemingly intended for other than sepulchral purposes.

Mountains.

Two lower ranges, named the Newry and Fathom Mountains, lie nearer the sea.

Indications of lead show themselves in several parts; traces of deserted mines of this mineral have also been discovered, but none are now wrought. Marble of good quality and some beauty is raised in large quantities near the city of Armagh. A blue stone, well adapted for building, is common in many places. The steatite or soap-stone has also been found; as likewise good potters' earth, brilliant cubic pyrites, and ironstone of very rich quality. Chalybeate springs in several parts point out the existence of iron; but this mineral has not been found in sufficient quantities to justify the outlay of money towards raising it. Pearls, the production of a species of shell-fish between the oyster and the muscle, have been found in the river Bann.

The county is well watered by numerous streams; the principal are the Callen, the Tynan, and the Tallwater, which fall into the Blackwater, a river that, after forming part of the boundary between this county and Tyrone, empties itself into the south-western angle of Lough Neagh. The Tara, the Newtown Hamilton, the Creggan, and the Fleury, flow into the Bay of Dundalk. The Cam or Camlin joins the Bann, which, rising in the Mourne Mountains, in the southern extremity of the county of Down, forms part of the western boundary of Armagh county, and falls into Lough Neagh to the east of the Blackwater. With the aid of a canal, the Bann is navigable for vessels of sixty tons burden through part of its course.

Lough Neagh, which stretches along the north of Armagh, is confined by it and the four counties of Down, Londonderry, Antrim, and Tyrone. It is of an oblong form, and is computed to cover 94,274 acres. Seven rivers and a number of smaller streams flow into it, while the only vent for its accumulated waters is through the channel of the northern Bann. Though estimable as a means of water communication through an extensive tract of country, it has little of the picturesque or romantic to attract attention. Ram Island, near the Antrim shore, and Derrywarragh, near the mouth of the Blackwater, are its only islands. Some parts of its shores have long been celebrated for the petrifying qualities of its waters. The cause of this phenomenon is not satisfactorily ascertained; for, though logs and branches of trees, in various stages of the petrificative process, have been found, this effect has not been produced on any pieces of timber laid there for the sake of experiment. Camlough and Lough Clay, the only lakes within the county, are of small dimensions.

Tillage cannot be said to be either in a very advanced or a very backward state. Farm manure is much used, but lime still more; which latter, though abundant in some parts of the county, is so scarce in others that it is drawn eight or ten miles for the purposes of tillage. It is chiefly burned with turf raised from bogs dispersed throughout most districts, but chiefly in the northern parts, where they are of fine quality and large dimensions. Fifty barrels of lime are allowed to the Irish acre. The chief succession of crops is oats repeated two or three seasons after potatoes or wheat, with manure. Green crops are every year more attended to, particularly among the wealthier farmers, and the gentry, who hold land in their own hands, and thus give a tone and example to the country for agricultural improvements.

The farms are in general very small, yet their owners are generally in circumstances of comparative comfort. There are few who do not keep at least one cow, or a few sheep; none but the poorest cottar is without a pig. Their usual diet is oatmeal, potatoes, and milk porridge, varied sometimes by salt herrings. The better description of farmers use animal food, chiefly bacon and poultry.

Armagh. Cheese in small quantity, and butter more than sufficient for domestic use, are obtained from their cows. Their sheep furnish wool, which is manufactured into the coarse cloths, blankets, and druggets, used by themselves and their families.

Line manufacture. The manufacture to which the industry of the country is chiefly directed, and which has given a peculiar tone to the character of the population, is the linen. It is no ways necessary to the promotion of this manufacture, that the spinners and weavers should be congregated in large towns, or united in crowded and unwholesome factories. On the contrary, most of its branches can be carried on in the cottages of the peasantry. The men devote to the loom those hours which are not required for the cultivation of their little farms; the women spin and reel the yarn during the intervals of their other domestic occupations. Every female servant is bound to produce a certain quantity of yarn weekly, in addition to her other duties. Smooth lawns, perennial streams, pure springs, and the open face of heaven, are necessary for perfecting the bleaching process. Hence the extensive bleachers, with all their assistants and machinery, dwell in the country. Such is the effect of this combination of agricultural occupations with domestic manufactures, that the farmers are more than competent to supply the resident population of the county with vegetable, though not with animal food; and some of the less crowded and less productive parts of Ulster receive a considerable supply of oats, barley, and flour from it. Apples are grown in such quantities as to entitle the county to the epithet bestowed on it, of the orchard of Ireland.

Manners. The cause now dwelt upon has had an effect equally striking on the manners and appearance of the people. The men are stout and well proportioned; nor does it appear that their growth is checked or their general health deteriorated by their early application to the sedentary and stooping labour of the loom. The women are generally handsome, and, in consequence of being chiefly employed within doors, fairer than those of other districts. On Sundays, and at fairs and similar places of resort, the dress and manners of both sexes indicate a superior degree of civilization. The interior of their cottages is neat, the exterior and the appendages cleanly. Cockfighting was once a favourite amusement among them, but the taste for it is rapidly declining. They delight in dancing, and have frequent meetings for the enjoyment of it; but hunting seems above all to be their darling recreation. The moment the cry of the hounds is heard, the labourer drops his spade, the weaver rushes from his loom, and the chase is followed with ardour and activity almost incredible; yet it rarely happens that redoubled exertions at their employments do not compensate for the time thus lost. Lively gratitude for favours, and a quick sense of injury or insult, yet seldom tinged with feelings of revenge, are leading characteristics of their moral temperament.

Religion. In the towns and level parts of the county the protestant religion, in its two principal forms of the established church and the presbyterian discipline, predominates; but the Roman catholic is prevalent in the mountainous and less cultivated parts. As far as may be conjectured from the returns of the commissioners of education, the Roman catholics appear to constitute nearly one half of the gross population.

Education. According to those returns, the number of children at school in 1824 amounted to 13,800. If the total number of children between five and fifteen years of age, which may be called the period of education, be 49,000, as stated in the population returns of 1821, upwards of two thirds of the whole remain uneducated. The religious persuasions

of those educated are as follows:—Established church 4655, presbyterians 2864, other dissenters 511, Roman catholics 5281. The number of schools is 333, of which 264, containing 9151 students, are supported wholly by the fees of the pupils; the remaining 69 are maintained either by grants of public money or by the voluntary contributions of the wealthier classes; viz. 44 schools, educating 3153 pupils, are supported by the former means, and 25 schools, educating 1540 pupils, by the latter.

The population, as may be inferred from the preceding Towns. statements, is chiefly rural. The county can boast but of four towns of more than 1000 inhabitants each, viz. Armagh city 8493; Lurgan 2715; part of Newry, the other and more populous part being in the county of Down, 2543; and Tanderagee 1158: total population of the larger towns 14,909. That of the remaining towns and villages, 17 in number, amounts but to 6987 souls; the rural population, therefore, is 175,431, being nearly in the ratio of 12 to 1 with respect to that of the larger towns, and of 8 to 1 with respect to that of the towns and villages of every description.

The city of Armagh is 82 miles north of Dublin, being **Armagh.** in 54° 20' 55" N. lat., and in 6° 37' 57" W. long. Though city. now much reduced in population, it was once considered as the metropolis of the island, and second only to Dublin in the number of its inhabitants. The honour of being its founder is attributed to St Patrick. It was built on an eminence named Druimsailech, or the Hill of Willows; its present name is supposed to be a slight corruption of Ard-macha, the High Place or Field. In 448 a synod was held here, the canons of which are still in existence. During the period anterior to the arrival of the English in Ireland, it suffered extremely from the assaults of the Danes, by whom it was repeatedly plundered and burnt. Nor was its condition much bettered by the change of masters. De Courcy, FitzAdelm, and De Lacy, pillaged it in turn in their attempts to subdue Ulster; and it was exposed to similar calamities during the wars by which the north of Ireland was desolated in the reign of Elizabeth. Her successor, James I., granted it a charter, according to which it has since been governed. Its decline was still farther increased by the non-residence of the archbishops, who, in consequence of the unsettled state of the northern province, fixed their residence for many years at Drogheda. From this deplorable state it was raised by Lord Rokeby, better known by the name of Primate Robinson. When he determined to make it the seat of his permanent residence, this venerable city was little more than a collection of cabins. He erected in it an archiepiscopal palace, a Public college or grammar school for classical education, a library buildings. now containing upwards of 12,000 volumes, and an observatory well furnished with astronomical instruments. Besides these, the city now contains a Roman Catholic chapel and a Presbyterian meeting-house, both on a large scale; and several places of worship for other religious denominations. Its other public buildings are, the cathedral, a cruciform building, more remarkable for its antiquity than its architectural beauty; the court-house, the Charitable prison, the charter-school, the barrack, the county infirmary, the lunatic asylum, and the fever hospital, which last was erected and is maintained at the expense of Lord John Beresford, the present primate. The number of poor relieved at the charitable institutions just mentioned amounted in the year 1829 to 2678, and occasioned an expenditure of L.2562. Besides these there are eleven dispensaries in various parts of the county, the returns from six of which give an aggregate of 9558 individuals relieved during the same year, at an expenditure of L.967, one moiety of which is derived from the contributions of individuals, the other from grants of public money. In

Armamæxi
||
Armenia.

Armagh city there is a mendicity society, which maintained 500 paupers during the same year, at an expenditure of L.584, being at the rate of L.1.3s. 4½d. each. The city is governed by a sovereign and twelve burgesses, who, when deaths occur, elect to the vacancies. The elective franchise is confined to the burgesses, and they uniformly return the archbishop's nominee as their representative. Although the linen trade has declined considerably, both here and throughout the north of Ireland, much of it is still manufactured in the vicinity of the city, and is disposed of at the market held here every Tuesday. (See Wakefield's *Ireland*; Barton's *Natural History of Lough Neagh*; Coote's *Statistical Survey of Armagh*; Shaw Mason's *Parochial Account of Ireland*, articles Creggan, Ballymoyer, and Seagoe; Erck's *Ecclesiastical Register*; Stewart's *History of the City of Armagh*; *Parliamentary Papers*; *Population Returns*, 1821; *Reports of Commissioners of Education*, 1814, 1824-26; *Report of Committee on the State of the Poor in Ireland*, 1830.)

ARMAMAXI, in *Antiquity*, a kind of Scythian chariots or carriages, composed of two wheels, variously adorned with crowns, shields, breastplates, and other spoils, carried in procession after the images of the gods and great men.

ARMATURA, in a general sense, is the same with what we otherwise call armour. It is more particularly used in the ancient military art to denote a kind of exercise performed with missile weapons, as darts, spears, arrows, and the like. In this sense armatura stands contradistinguished from palatia; the latter being the exercise of the heavy-armed, the former of the light-armed.

Ancient
Armenia.

ARMENIA, a country of Asia, anciently divided into Armenia Major and Minor. Armenia Major was bounded on the south by Mésopotamia, on the east by Media, on the north by Iberia and Albania, and on the west by the Euphrates. The most considerable cities were Artaxata, Tigranocerta, and Theodosiopolis. Armenia Minor was bounded on the east by the Euphrates; on the south by Mount Taurus, which separated it from Cilicia; on the west and north by a long chain of mountains, called in different places *Mons Scordiscus*, *Amanus*, and *Antitaurus*, by which it was separated from Cappadocia.

Armenia is said to have been very early advanced to the rank of a kingdom. Berosus makes one Sytha the first founder of this monarchy, whose successor Bardanes, he says, was driven out by Ninus, king of Assyria. The Armenians were in course of time subdued by the Medes, to whom Astyages made them tributaries, but allowed them to be governed by their own kings; but on the dissolution of the Median empire by Cyrus, the kingdom was reduced to the form of a province, and they were governed by Persian prefects or lieutenants. On the destruction of the Persian empire by Alexander the Great, Armenia fell into the hands of the Macedonians, to whom it continued subject till the beginning of the reign of Antiochus the Great. This prince having appointed two prefects, named Zadriades and Artaxias, to govern Armenia, they excited the people to a revolt, and caused themselves to be proclaimed kings of the provinces over which they presided. Antiochus being then very young, they succeeded beyond their expectation, which encouraged them to attempt the enlargement of their territories. Accordingly, invading the neighbouring countries, they took from the Medes the provinces of Caspiana, Phaunitis, and Basoropida; from the Iberians, Chorzena and Gogorena on the other side of the Cyrus; from the Chalybes and Mossynæci, the provinces of Pareneta and Herexena, which bordered on Armenia Minor. On this occasion the division of the kingdom into Armenia Major and Minor first took place. Artaxias became king of Armenia Major,

and Zadriades of Armenia Minor; and this distinction subsisted to later times.

By whom Artaxias was succeeded is not known; neither have we any account of the transactions of his reign, farther than that Antiochus led a powerful army against him and Zadriades, but without being able to recover a single province. Upon this he concluded a peace, designing to fall upon them at a proper opportunity; but they having entered into alliance with the Romans, by that means secured themselves in the possession of their kingdom. After this Artaxias was defeated and taken prisoner by Antiochus Epiphanes, but seems to have been restored to his kingdom.

From this time we meet with a chasm in the Armenian history for 70 years, during which all we know is, that Tigranes, the king's son, was delivered up as an hostage to the Parthians. On the news of his father's death, the Parthians set the young king at liberty, having first obliged him to give up a considerable part of his kingdom by way of ransom. Tigranes, thus restored to his father's kingdom, was prevailed upon in the beginning of his reign to enter into an alliance with Mithridates Eupator against the Romans, whose power began to give jealousy to all the princes of Asia. By their joint arms Cappadocia was conquered, and the son of Mithridates placed on the throne. Shortly after, the Syrians being harassed with a long and intestine war of the Seleucidæ, invited Tigranes to come and take possession of their country; which he accordingly did, and kept it for 18 years, till he was driven out by Pompey, and Syria reduced to the form of a Roman province. Encouraged by this success, he next invaded Armenia Minor, defeated and killed King Artanes, who opposed him with a considerable army; and in one campaign made himself master of the whole kingdom. From Armenia Minor he marched against the Asiatic Greeks, the Adiabeniens, the Assyrians, and the Gordians, carrying all before him, and obliging the people wherever he came to acknowledge him sovereign. From this second expedition he returned home loaded with booty, which he soon after increased by the spoils of Cappadocia, invading that kingdom a second time at the instance of Mithridates, who had been obliged by the Romans to withdraw his forces from thence. From Cappadocia, Tigranes, besides other booty, brought back into Armenia no fewer than 300,000 captives, having surrounded the country with his numerous forces in such a manner that none could escape. These, together with the prisoners he had taken in his two first expeditions, he employed in building the city of Tigranocerta, which they afterwards peopled.

In the mean time Mithridates, who had concluded a peace with the Romans for no other end than to gain time, sent a solemn embassy to Tigranes, inviting him to enter into a second alliance against the common enemy. This he at first declined; but in the end was prevailed upon by his wife Cleopatra to send him considerable supplies, though he never came heartily into the war, not caring to provoke the Romans, who on their part kept fair with him, taking no notice for the present of the supplies he had sent Mithridates. That unfortunate prince being soon after defeated by Lucullus, was forced to fly for shelter into Armenia, where he met with a very cold reception from his son-in-law, who would neither see him, treat with him, nor own him as his relation; however, he promised to protect his person, and allowed him in one of his castles a princely retinue, and a table suitable to his former condition.

Though this total overthrow of Mithridates might have opened the eyes of Tigranes, and made him oppose with all his might the growing power of the Romans, he fool-

Armenia. ishly left them to finish their conquest of Pontus, while he marched at the head of a very numerous army against the Parthians, with a design to recover from them the dominions they had formerly extorted from him before they set him at liberty. These he easily retook; and, not satisfied with what formerly belonged to him, he added to them all Mesopotamia, the countries that lay about Ninus and Arbela, and the fruitful province of Mygdonia; the Parthians, though at that time a mighty people, flying everywhere before him. From Mesopotamia Tigranes marched into Syria to quell a rebellion which had been raised by Cleopatra, surnamed *Selene*; who, after the death of her husband Antiochus Pius, reigned jointly with her sons in that part of Syria which Tigranes had not seized on. The malcontents were quickly reduced; and the queen herself was taken prisoner, and confined to the castle of Seleucia, where she was soon after put to death by the king's orders. From Syria Tigranes passed into Phœnicia, which he subdued either entirely or in great part, spreading far and wide the terror of his arms, inasmuch that all the princes of Asia, except those who were in alliance with the Romans, either in person or by their deputies submitted and paid homage to the conqueror.

The king having now subdued all Syria to the borders of Egypt, and being elated with a long course of victories and prosperous events, began to look upon himself as far above the level of other crowned heads. He assumed the title of *king of kings*, and had many kings waiting upon him as menial servants. He never appeared on horseback without the attendance of four kings dressed in livery, who ran by his horse; and when he gave answers to the nations that applied to him, the ambassadors stood on either side of the throne with their hands clasped together, that attitude being of all others then accounted among the orientals the greatest acknowledgment of vassalage and servitude. In the midst of all this haughtiness, however, he was unexpectedly visited by an ambassador from Lucullus the Roman general, who, without any ceremony, told him, that he came to demand Mithridates king of Pontus, who had taken refuge in his dominions, and, in case of his refusal, to declare war against him. Notwithstanding his high opinion of himself, Tigranes returned a mild answer to this message, in which, however, he refused to deliver up his father-in-law; and being highly provoked at Lucullus for not giving him the title of *king of kings* in his letter, he did not even bestow upon him the title of *general* in his answer. He now received with the greatest pomp imaginable his father-in-law Mithridates, whom till that time he had not admitted into his presence, though he had resided a year and eight months in his dominions. They had several private conferences; and at last Mithridates was sent back to Pontus with 10,000 horse, to raise there what disturbances he could.

Lucullus, on the other hand, hearing the king's resolution to protect Mithridates, immediately began his march for Armenia, at the head of only two legions of foot and 3000 horse, having left 6000 men in Pontus to keep that country quiet. Having passed the Euphrates without opposition, he detached two parties; one to besiege a city where he heard that Tigranes's treasure and concubines were kept; and the other, under Sextilius, to block up Tigranocerta, in order to draw the king to a battle. But Tigranes, after having put to death the scout that brought him the first intelligence of the approach of the Romans, made towards Mount Taurus, which he had appointed for the place of the general rendezvous. The Roman general then despatched Muræna in pursuit of the king; and having overtaken him in a narrow pass, defeated him, and, besides all the baggage, carried off a great many prisoners, the king himself having fled in the beginning of the skir-

Armenia. mish. After this he sent out several parties to scour the country, in order to prevent the innumerable forces of Tigranes from joining into one body. This, however, he was not able to effect: Tigranes was joined by such numbers of Gordians, Medes, Adiabeniens, Albanians, Iberians, &c. that before he left Mount Taurus, his army consisted, according to Plutarch, of 150,000 foot armed *cap-à-pié*, 35,000 pioneers, 20,000 archers and slingers, and 55,000 horse.

Lucullus was so far from being dismayed at this formidable army, that the only fear he had was lest the king should follow the advice of Mithridates, which was, not to engage the Romans, but, by ravaging the country, distress them for want of provisions. In order to draw him to a battle, therefore, he formed the siege of Tigranocerta, imagining that Tigranes would never suffer that fine city to be taken without making an attempt to relieve it. The event fully answered his expectations: Tigranes having called a council of war, it was unanimously resolved to attack the Romans; and Taxilis, whom Mithridates sent to dissuade the king from venturing a battle, was in danger of losing his head on account of the advice he gave. The Roman general finding Tigranes disposed to come to an engagement, left Muræna with 6000 men to carry on the siege, while he himself marched against the king's vast army with only 10,000 men according to some, and the highest computations make them no more than 18,000. The Romans were at first greatly disheartened; but being encouraged by Lucullus, they immediately broke the Armenian army, who betook themselves to flight almost at the first onset. The Romans pursued them till night, making a most terrible slaughter. Plutarch informs us, that of the Armenians 100,000 foot were killed, and that very few of the cavalry escaped; whereas of the Romans only five men were killed and 100 wounded. Antiochus the philosopher, mentioning this battle, says that the sun never beheld the like; and Livy, that the Romans never fought to such a disadvantage, the conquerors not amounting to a twentieth part of the conquered. Tigranes in his flight having met with his son in as forlorn a condition as himself, resigned to him his royal robes and diadem, desiring him to shift for himself and save those royal ensigns. The young prince delivered them to a trusty friend, who, being taken by the Romans, consigned them to Lucullus.

While the king was making his escape after this terrible overthrow, he was met by Mithridates, who was marching to his assistance at the head of a considerable army. The king of Pontus cheered up his son-in-law as well as he could, and encouraged him to continue the war; advising him, instead of fruitlessly bewailing the present disaster, to rally his troops, raise new supplies, and renew the war, not questioning but that in another campaign he might repair all the losses he had sustained: but while the two kings were consulting upon these matters, Lucullus made himself master of Tigranocerta. From this city he marched into the small kingdom of Gordyene, where he celebrated with the utmost pomp the obsequies of king Zarbienenus, whom Tigranes had put to death, lighting the funeral pile with his own hand. In this kingdom, besides immense sums of gold and silver, he met with such store of provisions as enabled him to carry on the war without putting the republic to any charge.

The two kings, having levied new forces, appointed their troops to rendezvous in the spacious plains on the other side of Mount Taurus; whereupon Lucullus leaving Gordyene, and passing by Mount Taurus, encamped close by the enemy. Several skirmishes happened for some time between the two armies without any considerable advantage; but Lucullus could by no means draw them

Armenia. to a general engagement. Upon this he decamped, as if he designed to march to Artaxata and lay siege to that place, where Tigranes had left his wife and children, with great part of his treasures. He had scarce formed his camp when the enemy appeared, and sat down close by him. Lucullus did not allow them to fortify their camp, but immediately attacked them, and having put them to flight after a faint resistance, pursued them all night with great slaughter, took most of the chief officers prisoners, and returned the next day loaded with booty.

The Roman soldiers now, finding the cold very severe, though it was no later in the year than the autumnal equinox, requested their general to allow them to retire into winter quarters. This request he rejected with indignation, upon which they mutinied. Lucullus did all he could to persuade them to continue in their duty; and prevailed so far that they consented to lay siege to Nisibis, in hopes of booty. This place they took; and Lucullus, to the great satisfaction of his troops, took up his winter quarters there. The next year, however, his forces again mutinied, accusing him of amassing immense wealth for himself; and, throwing their empty purses at his feet, told him, that as he enriched himself alone, he might carry on the war by himself. He endeavoured to appease them as much as possible; but the sedition being fomented by a party who favoured Pompey the Great, at that time aspiring to the command of Lucullus's army, the latter found himself obliged to sit still and see Mithridates and Tigranes overrun Cappadocia, and recover all Armenia and great part of Pontus. They would have gained much greater advantages, had not a son of Tigranes taken arms against his father, and obliged him to divide his troops. The father and son coming to a pitched battle, the latter was defeated, and forced to save himself in Parthia, where he persuaded Phraates, king of that country, to assist him with a numerous army against his father. Phraates having laid siege to Artaxata, Tigranes the elder was obliged to hide himself in the mountainous parts of his kingdom; upon which the king of Parthia returned home. Of this Tigranes the father being apprised, immediately abandoned the fastnesses of the mountains; and falling upon his son at Artaxata, dispersed the rebels with great slaughter, and entered his metropolis in triumph. Tigranes the son first fled to Mithridates; but finding him reduced to great straits, having been overcome a few days before, with the loss of 40,000 men, by Pompey, he went over to the Romans, and led them into Armenia against his father as an ally of Mithridates.

Tigranes being now thoroughly humbled, willingly yielded to the Romans, Cappadocia, Syria, Cilicia, and that part of Phœnicia which he possessed, contenting himself with his paternal kingdom; and not only paid the fine of 6000 talents laid upon him, but made large presents to Pompey, and all the officers of his army, which procured him the title of *the friend and ally of the Roman people*. He afterwards entered into a war with Phraates, king of Parthia, by whom he was overcome, and would have been driven out of his kingdom, had not a peace been brought about by the mediation of Pompey. He ever after cultivated a strict friendship with the Romans. He died in the 85th year of his age, and was succeeded by his son Artuades, called by Josephus *Artabazes*, by Orosius *Artabanus*, and by others *Artadistes*.

From this period to the time of Trajan, Armenia was governed by its own kings; but as they were plainly vassals to the Romans, though they did not take that title till the reign of the emperor Nero, their history falls to be considered under that of the Romans.

By Trajan the kingdom of Armenia Major was reduced to the form of a Roman province; but it soon recovered

its liberty, and was again governed by its own kings in the reigns of Constantine the Great and his successor, to whom the kings of Armenia were feudatories. In the reign of Justin II. the Saracens subdued and held it till the irruption of the Turks, who possessed themselves of this kingdom, and gave it the name of *Turcomania*. The Turks, after the reduction of Armenia, invaded Persia, and other countries subject to the emperors of the East; which gave the Armenians an opportunity of shaking off the Turkish yoke, and setting up kings of their own, by whom they were governed till the country was again subdued by Occadan, or, as some style him, *Heccata*, the son of Genghis, and first khan of the Tartars. The Armenians were still permitted, however, to have kings of their own; for in our chronicles we find mention made of Leo, king of Armenia, who in the reign of Richard II. came into England to sue for aid against the Turks, by whom he had been driven from his kingdom. In the year 1472 of the Christian era, Ussan Cassanes, king of Armenia, succeeding to the crown of Persia, made Armenia a province of that empire; in which state it continued till the year 1522, when it was subdued by Selim II., and made a province of the Turkish empire.

Respecting Armenia Minor, we find very little recorded, except what has been already mentioned, and what falls under the Roman history. It was made a Roman province by Vespasian, continued so till the division of the empire, when it was subjected to the emperors of the East; and, on the decline of their power, was subdued, first by the Persians, and afterwards by the Turks, who gave it the name of *Genech*, and have kept it ever since.

Modern Armenia comprises the greater part of the Armenia Major of the ancients, and is bounded on the north by Georgia and Mingrelia, on the west by the Euphrates, and on the south and east by the territories of Julamerick and the Persian province of Azerbaijan. It is divided among the Turks, Persians, and Kurds, though their territorial rights are not very distinctly defined; nor would it be possible to bind down the wandering tribes of Kurds to any fixed limits. The Turkish pachalics are, Erzeroum, Akiska, Khars, Bayazid, Moosh, and Diarbekir. Those pachalics are divided into districts. The country is mountainous; but the mountains are finely wooded, and are interspersed with extensive plains and beautiful valleys, which yield every kind of grain, and abundance of the most delicious fruits, such as grapes, olives, oranges, peaches, apricots, nectarines, mulberries, walnuts, melons, apples, and pears. Those fertile regions are watered by the Araxes, as well as by the Euphrates and Tigris, and by their numerous tributary streams, and present all the varieties of beautiful scenery which arise from the combination of wood, water, and mountains. Wax and honey are obtained in the mountains, as well as raw silk, hemp, cotton, and tobacco, which are exported to Constantinople and Russia. Manna is also produced in sufficient quantities to be exported. The mineral productions are, silver, copper, loadstone, saltpetre, sulphur, and bitumen. Wheat and barley are the two crops most extensively cultivated; and of these three successive crops may be obtained in two years. The principal manufactures and trade of this country consist in copper and iron, silk and cotton, wine, tobacco, and manna. The native Armenians are industrious and commercial in their habits, and evince a strong propensity to visit foreign countries. They form the commercial class in the Persian empire, as well as in Asiatic Turkey; and they are scattered in various other parts of the world, where they are engaged in extensive mercantile enterprises, and bear uniformly a high character for integrity in their dealings. The country contains several barbarous tribes, who are ruled by their own

Armenians independent chiefs, and who are addicted to plunder rather than to trade. Armenia contains several large towns, such as Erzeroum, with a population of 100,000; Diarbekir, Erivan, Van, population 50,000; besides others of inferior note, as Bayazid, Argish, and Betlis. Besides its numerous rivers, Armenia contains the great lake Van, the Arsisa of the ancients, which is 168 miles in circumference.

ARMENTIERES, a small handsome town in the department of the North, in France, containing 7600 inhabitants. It was taken by Louis XIV. in 1667, who dismantled it. The river Lys traverses the town, and forms a small harbour. Long. 3. 3. E. Lat. 50. 40. N.

ARMIERS, a town in France, in the department of the North, seated on the river Sambre. Long. 3. 45. E. Lat. 50. 15. N.

ARMIGER, a title of dignity belonging to such gentlemen as bear arms; and these are either by courtesy, as sons of noblemen, eldest sons of knights, &c.; or by creation, such as the king's servants, &c. See ESQUIRE.

ARMILLARY, in a general sense, something consisting of rings or circles.

ARMILLARY Sphere, an artificial sphere composed of a number of circles of the mundane sphere, put together in their natural order, to ease and assist the imagination in conceiving the constitution of the heavens and the motions of the celestial bodies. The armillary sphere revolves upon its axis within a silvered horizon, which is divided into degrees, and movable every way upon a brass supporter. The other parts are the equinoctial, zodiac, meridian, the two tropics, and the two polar circles.

ARMILUSTRIUM, in *Roman Antiquity*, a feast held among the Romans, in which they sacrificed, armed, to the sound of trumpets.

ARMINIANS, a religious sect, which arose in Holland, by a separation from the Calvinists. They followed Arminius, who, thinking the doctrine of Calvin with regard to free-will, predestination, and grace, too severe, began, in the year 1591, to express his doubts concerning them; and upon further inquiry adopted sentiments more nearly resembling those of the Lutherans. After his appointment to the theological chair at Leyden, he thought it his duty to avow and vindicate the principles which he had embraced; and the freedom with which he published and defended them exposed him to the resentment of those that adhered to the theological system of Geneva, which then prevailed in Holland; but his principal opponent was Gomar, his colleague. The controversy which was thus begun, became more general after the death of Arminius, in the year 1609, and threatened to involve the United Provinces in civil discord. The Calvinists, or Gomarists as they were now called, appealed to a national synod. Accordingly the synod of Dort was convened by order of the States General, in 1618, and was composed of ecclesiastical deputies from the United Provinces, as well as from the reformed churches of England, Hesse, Bremen, Switzerland, and the Palatinate. The principal advocate in favour of the Arminians was Episcopius, who at that time was professor of divinity at Leyden. It was first proposed to discuss the principal subjects in dispute, and that the Arminians should be allowed to state and vindicate the grounds on which their opinions were founded: but some difference arising as to the proper mode of conducting the debate, the Arminians were excluded from the assembly, their case was tried in their absence, and they were pronounced guilty of pestilential errors, and condemned as corrupters of the true religion. In consequence of this decision they were treated with great severity, they were deprived of all their posts and employments, their ministers were silenced, and their congregations were suppressed. However, after the death of

Prince Maurice, who had been a partisan of the Gomarists, in the year 1625, the Arminian exiles were restored to their former tranquillity; and, under the toleration of the state, they erected churches and founded a college at Amsterdam, appointing Episcopius to be the first theological professor. The Arminian system has very much prevailed in England since the time of Archbishop Laud, and its votaries in other countries are numerous.

The Arminians are also called *Remonstrants*, from a humble petition, entitled their *Remonstrance*, which, in the year 1610, they addressed to the states of Holland. Their principal writers are Arminius, Episcopius, Vorstius, Grotius, Curcellæus, Limborch, Le Clerc, and Wetstein; not to mention many others of more modern date.

ARMINIUS, JAMES, whose real name in Low Dutch was James Harmanni, a famous Protestant divine, was born at Oude water, in Holland, in 1560. He was ordained minister at Amsterdam on the 11th of August 1588, where he soon distinguished himself by his sermons, which were remarkable for their solidity and learning. Martin Lydias, professor of divinity at Franeker, judging him a fit person to refute a writing in which Beza's doctrine of predestination had been attacked by some ministers of Delft, Arminius at his desire undertook the task; but upon thoroughly examining the reasons on both sides, he came into the opinions he proposed to overturn, and afterwards went still farther than the ministers of Delft had done. In 1600 he opposed those who maintained that ministers should subscribe the confession and catechism every year. In 1602 a pestilential disease raged at Amsterdam, during which he acted with the greatest resolution and courage, in assisting the poor and comforting the sick; and Lucas Trelocatius and Francis Junius dying of that disease at Leyden, the curators of that university chose Arminius professor of divinity there, and he was afterwards made doctor of divinity. Disputes upon grace were soon after kindled in that university; and he was at length engaged in a new contest, occasioned by a disputation of his concerning the divinity of the Son. These contests, his continual labour, and the concern of seeing his reputation blasted by a multitude of slanders in relation to his opinions, impaired his health, and threw him into a fit of sickness, of which he died on the 19th of October 1609. Arminius was esteemed an excellent preacher; his voice was low, but very agreeable; his pronounciation admirable; he was easy and affable to persons of all ranks, and facetious in conversation amongst his friends. The curators of the university of Leyden had so great a regard for him, that they settled a pension upon his wife and children. He left several treatises, viz. 1, Disputationes de Diversis Christianæ Religionis Capitibus; 2, Orationes, itemque Tractatus Insigniores aliquot; 3, Examen modesti Libelli Gulielmi Perkinsi de Prædestinationis Modo et Ordine, itemque de Amplitudine Gratiæ Divinæ; 4, Analysis Capituli Noni ad Romanos; 5, Dissertatio de vero et genuino Sensu Capituli Septimi Epistolæ ad Romanos; 6, Amica Collatio cum D. Francisco Junio de Prædestinatione, per literas habita; 7, Epistola ad Hippolytum a Collibus. These pieces were collected in a 4to volume, published at Leyden in 1629, which has been several times reprinted.

ARMISTICE, in military affairs, a temporary truce or cessation of arms for a very short space of time. The word is Latin, *armistitium*, and compounded of *arma*, arms, and *sto*, to stand or stop.

ARMOISIN, a silk stuff, or kind of taffety, manufactured in the East Indies, at Lyons in France, and at Lucca in Italy. That of the Indies is slighter than those made in Europe.

ARMORIC, or AREMORIC, something that belongs to the province of Bretagne or Britany, in France. The

Armour
||
Armstrong.

name *Armorica* was anciently given to all the northern and western coast of Gaul, from the Pyrenees to the Rhine, under which name it was known even in Cæsar's time. The word is of Bas-Breton origin, and signifies *maritime*; compounded, according to M. Menage, of *ar*, upon, and *more*, sea.

ARMORY, a storehouse of arms, or a place wherein military habiliments are kept, to be ready for use. There are armories in the Tower, and in all arsenals, citadels, castles, &c.

ARMOUR, a defensive habit, wherewith to cover and secure the body from the attacks of an enemy. In ancient statutes this is frequently called *harness*. A complete armour anciently consisted of a casque or helm, a gorget, cuirass, gauntlets, tasses, brassets, cuishes, and covers for the legs, to which the spurs were fastened. This formed armour *cap-à-pié*, and was used by the cavaliers and men-at-arms. The infantry had only part of it, viz. a pot or headpiece, a cuirass, and tasses; but all light. Lastly, the horses themselves had their armour, wherewith to cover the head and neck. Of all this furniture of war, scarce any thing is now retained except the cuirass; the gorget or neck-piece worn by officers being at present only a badge of honour, and of no defence.

ARMOUR, *Coat*, is the escutcheon of any person or family, with its several charges, and other furniture; as mantling, crest, supporters, motto, &c. Thus we say, a gentleman of coat armour, meaning one who bears arms.

ARMS, ARMA, in a general sense, includes all kinds of weapons, whether for defence or offence. Arms of stone and of brass appear to have been used before those of iron and steel. Josephus assures us that the patriarch Joseph first taught the use of iron arms in Egypt, arming the troops of Pharaoh with a casque and buckler. What contributed most to render the Romans masters of the world was, that having successively warred against all nations, they constantly renounced their own methods, arms, &c. wherever they met with better. Thus Romulus, during his war with the Sabines, a bold and warlike nation, adopted their broad buckler, in lieu of the small Argian buckler, which he had used till that time.

ARMS, or *Armories*, in *Heraldry*, marks of dignity and honour, regularly composed of certain figures and colours, given or authorized by sovereigns, and borne on banners, shields, coats, &c. for the distinction of persons, families, and states, and passing by descent to posterity. They are called *arms*, in regard they were borne principally on the buckler, cuirass, banners, and other apparatus of war. They are also called *coats of arms*, *coat armour*, &c. because anciently embroidered on surcoats, &c. See HERALDRY.

ARMSTRONG, JOHN, M.D. an eminent physician, poet, and miscellaneous writer, was born in Castletown parish, Roxburghshire, where his father and brother were ministers; completed his education in the university of Edinburgh, where he took his degree in physic, February 4, 1732, with much reputation; and published his thesis, as the forms of that university require; the subject of which

was *De Tabæ Purulenta*. In 1735 he published a little humorous fugitive pamphlet in 8vo, entitled *An Essay for abridging the Study of Physic; to which is added, a Dialogue betwixt Hygeia, Mercury, and Pluto, relating to the practice of Physic as it is managed by a certain illustrious Society; as also an Epistle from Usbeck the Persian to Joshua Ward, Esq.* This piece contains much fun and drollery; in the dialogue, he has caught the very spirit of Lucian. In 1737 he published *A Synopsis of the History and Cure of the Venereal Disease*, 8vo. This was soon followed by the *Economy of Love*, a poem which has much merit, but, it must be confessed, is too strongly tinged with the licentiousness of Ovid. It is said, however, that his maturer judgment expunged many of the luxuries of youthful fancy, in an edition "revised and corrected by the author" in 1768. It appears by one of the cases on literary property, that Mr Millar paid 50 guineas for the copy-right of this poem, which was intended as a burlesque on some didactic writers. It has been observed of Dr Armstrong, that his works have great inequalities, some of them being possessed of every requisite to be sought after in the most perfect composition, while others can hardly be considered as superior to the productions of mediocrity. *The Art of preserving Health*, which was published in 1744, is his best performance. In 1746 Dr Armstrong was appointed one of the physicians to the hospital for lame and sick soldiers behind Buckingham House. In 1751 he published his poem *On Benevolence*, in folio; and in 1753, *Taste, an Epistle to a young Critic*. In 1758 appeared *Sketches or Essays on various subjects, by Launcelot Temple Esq. in two parts*. In this production, which possesses much humour and knowledge of the world, and which had a remarkably rapid sale, he is supposed to have been assisted by Mr Wilkes. In 1760 he was appointed physician to the army in Germany, where, in 1761, he wrote a poem called *Day, an Epistle to John Wilkes of Aylesbury, Esq.* In this poem, which is not collected in his works, he wantonly hazarded a reflection on Churchill, which drew on him the vengeance of that severest of satirists. In 1770 Dr Armstrong published a collection of Miscellanies, in 2 vols., containing, 1, The Art of preserving Health; 2, Of Benevolence, an Epistle to Eumenes; 3, Taste, an Epistle to a young Critic, 1753; 4, Imitations of Shakspeare and Spenser; 5, The Universal Almanack, by Nouredin Ali; 6, The Forced Marriage, a tragedy; 7, Sketches. In 1771 he published *A short Ramble through some parts of France and Italy, by Launcelot Temple*; and in 1773, in his own name, a quarto pamphlet, under the title of *Medical Essays*; towards the conclusion of which he accounts for his not having such extensive practice as some of his brethren, from his not being qualified to employ the usual means. He complains much of the behaviour of some of his brethren, of the herd of critics, and particularly of the reviewers. He died in September 1779.

ARMUYDEN, a seaport town of the United Provinces, in the island of Walcheren, formerly very flourishing, but now inconsiderable. Long. 3. 40. E. Lat. 51. 30. N.

Any-
Dini-
tis.

AN army, says Dr Johnson,¹ is "a collection of armed men obliged to obey one man." This definition, however, has little else than its brevity to recommend it. An army, it is true, is "a collection of armed men," and such a "collection" is generally "obliged to obey one man," that is to say, it is commonly placed under the exclusive control and direction of an individual chief or leader. But it does not follow that "a collection of armed men obliged to obey one man" is the distinguishing or principal characteristic of an army, since a gang of robbers or banditti would equally answer this description. To be at all applicable, therefore, the definition of army must be at once more comprehensive and more precise; in other words, it must include the specification of those peculiar circumstances or attributes, the aggregate of which constitutes the complex idea sought to be resolved. Hence an army may, we think, be more accurately defined, a certain portion of the community selected, raised, or assembled, for the defence of the state, by means of conscription, voluntary enrolment, tenure of military service, or otherwise; armed, disciplined, and organized, conformably to a given system, which is considered best calculated for giving full development and efficacy to its collective force; and commanded by a chief or leader, with subordinate officers in regular gradation, to carry his orders into effect, and move the living machine, thus constructed, as he shall think proper to direct. It is an artificial or scientific combination of a great number of powers, individually small or insignificant, so as, by their union and concentration, to accomplish mighty and important deeds; a force which states and nations create out of the elements of their strength, as mechanics form engines by taking advantage of and skilfully combining the action of the primary mechanical powers; an instrument, in short, so contrived as, though originally intended for the best, to be equally available for the worst purposes, being alike fitted for defence or aggression, for protection or conquest, for restraining and punishing the dishonest ambition of others, or affording the means of gratifying our own. An army, therefore, may be considered a species of movable engine, composed of a vast number of individual parts or powers, so arranged and organized as not only to act in concert, but to exert their whole aggregate force in any direction and upon any point which may be ordered or required. At the present day this denomination is applied to any given number of soldiers, consisting of artillery, infantry, and cavalry, of various descriptions, all completely armed and provided with engineers, a train of artillery, ammunition, magazines, commissariat, and other necessary adjuncts, subject to the command of a general, having under him lieutenant-generals, major-generals, brigadier-generals, colonels, majors, captains, and subalterns.² And an army is now composed of battalions or squadrons, regiments, brigades, divisions, and sometimes corps d'armée; two or more battalions or squadrons forming a regiment, two or more regiments a brigade, two or more brigades a division, and two or more divisions a corps d'armée. So much for definition and description.

General
observa-
tion

Were we called upon to trace to its origin the history of war, we should find it necessary to ascend through every form and gradation of society to the very cradle

of the human race. Admitted on all hands to be one of the greatest evils, war is also, unhappily, one of the oldest. "Il est triste d'imaginer," says a celebrated military writer, "que le premier art qu'aient inventé les hommes, ait été celui de se nuire, et que, depuis le commencement des siècles, on ait combiné plus de moyens pour détruire l'humanité que pour la rendre heureuse."³ This is a truth which cannot be disputed. The passions of rivalry, jealousy, hatred, revenge, cupidity, thirst of power or ambition, were born with the world; and these, in their turn, gave birth to war, which again produced the desire of conquering or combating with success. But, in proportion as this desire came to prevail, men would naturally be led to reflect as to the means best fitted to insure its gratification: and as experience must soon have convinced them that the battle was not always to the strong, nor the race to the swift,—or, in other words, that mere brute force, openly applied, was in many cases insufficient to secure the victory, and, in most, productive of a loss that countervailed it,—they must early have discovered that some degree of combination was requisite, and certain extrinsic qualities necessary, to render it effectual; that violence might find an auxiliary in cunning, and resistance be paralysed by stratagem and surprise. Such, accordingly, is the state of things which generally obtains amongst savage tribes, however warlike and enterprising. They seldom go down to battle openly and boldly; nor do they consider victory, when dearly purchased, as either honourable or desirable. Artifice is their main resource. The first principle of their simple tactics is to steal unperceived upon the enemy, and overwhelm him, while unsuspecting of attack and unprepared for resistance. In this and similar principles, however, we discover the origin and primary development of the military art. Its source is in the forest or the wilderness. But as war is the first art which men invented, so it is also that which was soonest cultivated and improved. It kept pace with the progress of society;—as mankind multiplied, and communities extended themselves, it received a corresponding expansion;—more means were combined, and a greater number of men were assembled. This was the second stage of the art, where it remained long stationary, and in nearly the same state in which we find it at the present day among some of the Asiatic nations. Science had not digested nor systematized the rude and shapeless mass of knowledge which experience had supplied, or suggested new combinations of existing means. But ambition at length gave a fresh stimulus to improvement, by opening up a new theatre for its expansive energies; and successive conquerors contributed largely to the cultivation of an art which became the instrument of their glory. In their hands, accordingly, it determined the destiny of nations;—it raised up or destroyed empires;—it produced mighty revolutions;—it overthrew old dynasties, and created new ones in their stead;—and, amidst all the havoc and desolation occasioned by the pursuit of false glory, it contributed, upon the whole, to the cultivation of those sciences and arts which have a tendency to mitigate the natural ferocity of man, and ultimately to render conquest itself less destructive, and war less sanguinary.

Army.

Results so vast leave no doubt whatever, that the art which was principally instrumental in producing them, must have made considerable progress at a very remote period of the world. It is in fact in the early and semi-barbarous stage of society that the military virtues are found in the greatest perfection. The mind is then fierce, ardent, energetic, and daring; peculiarly accessible to the illusion of warlike renown, and undistracted by any of those influences or impressions which act so powerfully upon man in civilized life; while the body, unpampered by luxury, unenfeebled by indulgence, is a fit companion for such a spirit, and capable of enduring, without difficulty, the fatigues and privations incident to war. Add to this that, at the period of which we speak, the only law generally recognised and respected is the law of the strongest; that the necessity of self-defence, of protecting person and property from violence and spoliation, keeps men continually prepared to repel force by force, or to retaliate one aggression by another; that, consequently, the disorders which distract society re-act upon and foster the turbulent spirit in which they have their origin; that war thus becomes a trade which all are either disposed or compelled to pursue; that, to bold and adventurous spirits, it opens up the only path which leads to fortune and to fame, and thus holds out irresistible temptations to embark in military enterprises. At such a period all men are soldiers, and war is their natural employment; in it they live and move and have their being. But necessity is the parent of invention, and the mother of arts; and to it the science of war was indebted for its first improvements. Armies are unwieldy machines, which cannot be moved without some degree of organization, nor supported without considerable care and foresight, nor led into action with an enemy without a certain knowledge of tactical combinations. It is obvious, therefore, that wherever we read of such masses of men having been assembled, whether for purposes of aggression or defence, we may safely consider this fact as of itself conclusive, that the military art had there reached the second stage of its progress, or, in other words, had made considerable advances. History may be silent as to the precise extent to which improvement had been carried, and the records of the past may afford no clue to direct our inquiries concerning the composition and organization of the armies of remote antiquity; but if it be once admitted that such armies existed, and that they defended some countries and overran or conquered others, this admission will imply no inconsiderable knowledge of the art of war on the part of those by whom they were organized and directed.

Discipline of some kind or other is the bond which keeps together large bodies of men: without it they are a mere mob or rabble, incapable alike of action or direction, and formidable to none save the people of the country where they happen to have congregated. Even the Tartar hordes of Genghis Khan and Timour had an organization and discipline of their own, by means of which these barbarian conquerors were enabled to impel their fierce and warlike masses against the enfeebled and effeminate soldiery of countries advanced in wealth and in civilization,¹ and the same observation applies still more forcibly to the Asiatic and Turkish armies of our own time. In a word, we may adopt with some qualification the remark of Guibert, when speaking of the progress of the military art: "Il précéda," says he, "chez tous les peuples, les arts et les sciences, et y périt à mesure que celles-ci s'étendirent."² The details into which we are about to enter will fully illustrate the truth of these general observations.

The earliest military establishment of which history has preserved any record is that of Egypt under the reign of Sesostris, or, as he is denominated in the monumental sculptures of that wonderful country, Rhamses,³ who was considered the greatest of the Egyptian kings after Osiris,⁴ and has generally been supposed by chronologists to have flourished about seventeen centuries before our era.⁵ But Osiris was an ideal being, the offspring of mythology, and the hero of fable, adored by the Egyptians sometimes as a deified mortal, sometimes as a personification of the Nile, and sometimes as the symbolical representative of the solar orb. Sesostris, on the contrary, is claimed by history as a real personage; and although the accounts which have been preserved of the reign of this prince, chiefly by the Greek historians, are dashed with a considerable admixture of exaggeration and romance, we cannot reasonably doubt the existence of the monarch, however we may be inclined to question the exploits of the hero and the achievements of the conqueror. The substance of these accounts, indeed, when considered in connection with the corroborative evidence supplied by the Egyptian monuments, and the traces of his expedition which remained even in the age of Herodotus, may be regarded as the more deserving of credit that, while scepticism has little to oppose to them except its own incredulity, the statements of the Greek historians are not only consistent with one another, but in strict accordance with the uniform tradition and belief, as well as with the records, of that country, the mother of arts and civilization, which, under this renowned

¹ Timour or Tamerlane, of whom unfortunately we know so little, has left an institutional or elementary treatise on war and the art of conducting armies, each page of which affords proof of a natural genius for commanding men, as well as of tact and skill in employing them to the best advantage. See *Instituts de Timour*, par Langlès; also Jomini, *Traité des Grandes Opérations Militaires*, tome viii. p. 678. Paris, 1816.

² *Essai Général de Tactique*, vol. i. p. 60.

³ One of the difficulties which occur in our inquiries concerning Sesostris arises from the different names by which he has been designated by ancient writers. He has been variously called Sesostris, Sesoosis, Sesochis, Sesonchosis, Sethosis, Sethos, Ramesses, Rameses, Rhamses, Ramestes, Rampses, Vexores, and Ægyptus. But most of these appellations were probably titular. Thus, *Sesostris* may be SE-SIOS-T-RE, which signifies, *filius domini, donum solis*; *Sesoosis* may, in like manner, be a corruption for SE-SIOS-STOS, *filius domini dominorum*; and *Rhamses* or *Ramesses*, derived from RE, *sol*, and MES, *gignere*, may signify *Begotten by the Sun*. But it is not always possible to render ancient Egyptian names according to the grammatical rules established in the Coptic language, and, therefore, such etymologies as those now proposed are to be received as purely conjectural. The common designation of this monarch on the monuments is RAMESES-MEIAMOUN, *Rhamses beloved of Ammon*; or, adopting the etymology of *Rhamses* just proposed, *Begotten by the Sun, Beloved of Ammon*; in which case both appellations would be merely titular. Vide Sir W. Drummond's *Origines*, book iv. chap. 13, and Champollion's *Précis du Système Hiéroglyphique*, p. 223. Paris, 1824.

⁴ Manetho apud Euseb. *Chron. lib. i.* In Manetho apud Josephum contra Apionem, lib. i. p. 1053, this monarch is indifferently called *Ramesses* and *Rampses*.

⁵ Chronologists have been unable to fix the precise date of the reign of Sesostris. Larcher, the celebrated translator of Dionysius of Halicarnassus, adopts and defends with much warmth the chronography of Herodotus; while others, rejecting the authority of the father of history, endeavour to determine the era of the Egyptian monarch from the scanty data furnished by Diodorus or Strabo. The objections to the conclusions of Larcher, stated by Sir William Drummond in his *Origines*, book iv. chap. 13, appear to be perfectly unanswerable.

sovereign, is supposed to have reached an unprecedented height of military glory.

Sesostris, however, did not create the military spirit to which he appears afterwards to have given such ample development. This was in a great measure the work of his father, Amenophis III., who, shortly after the birth of his son, is said to have assembled all the male children born on the same day, and to have given them the same education. No distinction was made between the young prince and his companions. They were alike engaged in the same studies, trained to the same exercises, inured to the same hardships, and instructed in the use of the same arms. A rigid discipline prescribed unremitting exertion, while daily privations and fatigue hardened and prepared them for the duties of war. In establishing this military seminary, Amenophis appears to have intended placing around his son a faithful band of soldiers, attached to him by the associations of early friendship, and the ties of brotherhood in arms. Nor did the result disappoint his expectations. Arrived at manhood, the prince and his companions soon convinced how much they had profited by their education,—how well they merited the confidence reposed in them. With bodies rendered vigorous and athletic by labour and exercise, and with minds cultivated by the best studies, they were already fitted to act both as soldiers and as generals, to serve with energy, or to command with skill. Sent by his father at an early age to command an expedition against the Arabians, the prince, accustomed, as well as his companions, to suffer long both from hunger and from thirst, could meet upon equal terms the wandering and yet unconquered tribes, who chiefly trusted for their defence to the barrenness of their inhospitable deserts. Arabia was subdued and annexed to the Egyptian monarchy. He afterwards directed his march to the west, and his father lived to see the greater part of Libya conquered by his victorious son. When Sesostris mounted the throne, therefore, his military fame was established. The qualities of his mind, his dauntless courage, and his daring ambition, seemed to be announced by his personal appearance; and the people, no doubt, easily associated the character of the hero with the robust frame and gigantic stature¹ of their new monarch. But it is more material to state, that the success of his arms, in his wars with the Arabians and Libyans, had inspired him with the hopes of making yet more extensive conquests; and, if we may credit the Greek historians, the perilous project of subjugating the world must have been already familiar to the mind of Sesostris when he succeeded to the crown. Amidst the burning sands of Libya, and in the depth of the Arabian deserts, the phantom of universal empire showed itself, and he vowed to pursue it.²

His resolution being thus taken, no time appears to have been lost by the new sovereign in preparing his subjects for an enterprise, which could not be undertaken but in defiance of all the counsels of prudence. He caused various reports to be spread abroad, artfully attributing his project to other causes than his own ambition. His daughter Athyrtis, famed for her wisdom, as a sort of Egyptian Cassandra, proclaimed the facility with which her father would conquer the earth: the success of the enterprise was prognosticated by omens, by sortilege, and by divination: and the people were reminded that, at the birth of Sesostris, Phtha had appeared to his father in a dream, and had predicted to Amenophis that the new-

born boy should one day become master of the world.³ Nor did the Egyptian king content himself with influencing opinion in his favour by means of prophecies, prodigies, and visions. His natural sense taught him that other and more rational precautions were necessary; that a king who is not popular at home, should not think of making conquests abroad. His first object, therefore, was to secure the affections of the Egyptians: and for this purpose he employed all those arts which, exercised by sovereigns, are so powerful in conciliating popular favour. Some he won by his munificence, others by his clemency; the selfish were secured by his liberality, the vain were flattered by his condescension and affability; even traitors to the royal authority were allowed to escape with impunity, and public debtors were liberated from the prisons in which they were confined.⁴ On the other hand, that he might provide for the tranquillity of his kingdom, and leave none behind him who either would or could attempt a revolution in his absence, he made a partition of power among the chief men of the nation, dividing the whole territory of Egypt into thirty-six nomes or prefectures, over which he appointed as many governors, each of whom was charged with the collection of the royal revenues, and the administration of the laws within his own particular district. He at the same time elevated his brother Armais to the rank of regent of the kingdom; and, except that this prince might not wear the royal diadem, he was permitted to assume all the pomp of a monarch; an indulgence which he so far abused as to usurp the crown in the king's absence, and to attempt his life on his return home from his long and perilous expedition.⁵

Having completed these and other necessary arrangements, Sesostris next proceeded to raise an army. The peace establishment of the kingdom, as previously organized by this prince, appears to have consisted of a numerous militia, divided into two classes, denominated *kalsires* and *harmatopoi*, and amounting, according to Herodotus, to 410,000 men, distributed throughout the different provinces as a species of military colonists, each man being allowed a portion of land adequate to the maintenance of himself and family. This formed the nucleus of the mighty force which Sesostris now raised for the conquest of the world, consisting, if we may believe Diodorus Siculus, of 600,000 infantry, 24,000 cavalry, and 27,000 war chariots; a force certainly equal to the magnitude of the enterprise in which he was about to engage, though it is difficult to conceive how the population of a small country like Egypt, supposing it ever so dense, could have supplied so vast a body of men, exceeding, by more than 200,000, the numerical strength of the army with which the Emperor Napoleon invaded Russia, and which was by far the largest ever assembled in modern times. No precise information has reached us as to the composition, organization, and discipline of this expeditionary army. We only learn, incidentally as it were, that the king chose as the leaders of his less experienced troops, the companions of his youth, trained, like himself, to the use of arms, and exceeding 1700 in number; that disgrace or infamy was attached to disobedience of orders and neglect of duty, and that meritorious or valorous deeds were liberally rewarded; circumstances which, taken in connection with the particulars above stated, seem to warrant the conclusion, that the military system of Egypt had reached no small degree of improvement, and that the science of war, in all its branches, had made considerable advances. With

¹ Sesostris was four cubits and four palms, or about seven feet in height, and seemed formed by nature to sustain all the toils and fatigues to which his active life was afterwards exposed. Diodorus, lib. i. sect. 55.

Army.

a view to the ulterior objects of the expedition, Sesostris also collected or fitted out a fleet of 400 sail; and the ships are said to have been of large dimensions, adapted to the purposes both of war and transport.¹

With these immense preparations the warlike monarch at length commenced his perilous enterprise. He invaded Ethiopia, and compelled the inhabitants to pay him a tribute in ebony, gold, and ivory. Even the ferocious Troglodytes yielded to the conqueror. Advancing farther to the southward, he passed the frontiers of Ethiopia, and entered the country extending beyond Sennar to the Mountains of the Moon, where he left various monuments both of his power and of his piety. In the Straits of Dira or Babelmandeb he joined his fleet, consisting, as above stated, of 400 sail, which had already compelled the inhabitants of the islands in the Erythrean Sea, and of the adjacent continent, to acknowledge his authority. The victorious monarch next proceeded to India, which he completely overran, extending his conquests beyond the Ganges, and subduing some of the countries which lie between that river and the Eastern Ocean. He then directed his course towards the country of the five rivers or Punjab; crossed the immense reticulation of streams, which ultimately unite their waters with the Indus; and ascended the table-land of central Asia. Nor were the Scythian nations able to resist the torrent as it rolled westward through Tartary, behind the mountains of Imaus, and north of the Caspian, to the river Tanais and the Palus Mæotis. Having entered Europe, Sesostris passed through Sarmatia, Dacia, and Mæsia, nor halted until he arrived in Thrace, where he erected columns to perpetuate the memory of his victories, and to prove the extent of his conquests. From Thrace he crossed over into Asia Minor, and advanced into the plains of Colchis (rendered so famous in Grecian story by the expedition of the Argonauts and the fable of the golden fleece), where he founded a colony on the banks of the Phasis, and erected monuments, some of which were in existence in the age of Herodotus. He then marched against the Assyrian empire, which he conquered, and thus seated himself on the throne which had been occupied by Ninus and Semiramis. Finally, surrounded with the trophies of victory, and enriched with the spoils of nations, Sesostris returned to Egypt in triumph, after having been thirty years engaged in an expedition, undertaken in defiance of all the dictates of prudence, yet, if we believe the concur-

rent testimony of historians, terminated without a single reverse of fortune.² Such is the military story of the renowned Rhamses.³ That it involves many improbabilities is obvious; but what portion of ancient history is free of them? Mankind, in every age of the world, have taken delight in the marvellous; and if the ancients appear to have been pleased with reading romances in history, the moderns seem equally disposed to read history in romances. The great difficulty in forming an accurate judgment as to the story of the Egyptian monarch arises from the total want of details. We hear nothing of the generals to whom he was opposed, of the cities which he besieged, nor even of the battles which he fought. Historians relate his triumphs, but are silent respecting the skill which obtained them. At the same time, it cannot reasonably be doubted, we think, that there is a large substratum of truth in the narratives which have reached us respecting this extraordinary personage. By the concurrent testimony of the ancient authors, confirmed by the evidence derived from the Egyptian monuments, he is represented as a great warrior and conqueror; as the first, and, we may almost add, the last, of the Pharaohs who pursued the phantom of military renown, and sought for glory in distant expeditions: nor are there wanting circumstances which warrant the conclusion, that he overran some countries, conquered others, and left traces of his progress in many parts both of Asia and Europe. That he established a regular army, and provided a fleet to co-operate with it in his expedition against the countries of the East, are facts which seem to be as well attested as any in ancient history.⁴

"C'est chez les peuples d'Asie, chez les Perses sur-Persian tout," says Guibert, "que l'art de la guerre commença à armies. prendre quelque consistance;" but he adds, "après la mort de Cyrus, le luxe lui fit quitter la Perse, et il passa chez les Grecs."⁵ This remark, however, must be taken with some important qualifications. As a general proposition, it is doubtless true that the military art first assumed consistance among the Asiatic nations, particularly the Persians; for the warlike spirit of Egypt seems to have expired with its first and only conqueror. But it is utterly absurd to maintain that the death of Cyrus was productive of any change in the military system of Persia, or that this event led to the transference which Guibert has so gratuitously supposed. Cyrus, in as far as we are able to distinguish his character, and form a judgment

¹ *Origines, ubi supra.*

² Diodorus, lib. i. sect. 54 and 55; Strabo, lib. xvi.; Herodotus, lib. ii. c. 103 and 110; Manetho *apud Joseph. contr. Apion.*; Julius Africanus *apud Syncellum.* In all the countries through which he passed, Sesostris left monuments behind him; and where he encountered serious resistance, the columns he erected bore this inscription: "Sesoosis, King of Kings, and Lord of Lords, has subdued this region by force of arms." Diodorus, *ibid.*

³ The information given to Germanicus when he visited the ruins of Thebes, by some of the elder Egyptian priests, relative to this monarch, and the military establishment he had created, is thus recorded by Tacitus in the second book of his Annals: "Mox (Germanicus) visit veterum Thebarum magna vestigia; et manebant structis molibus litteræ Egyptiæ, priorem opulentiam complexæ; jussusque e senioribus sacerdotum patrium sermonem interpretari referebat habitasse quondam septingenta millia ætati militari: atque eo cum exercitu regem RHAMSEN Libya, Æthiopia, Medisque et Persis, Bactriano ac Scythia potitum; quasque terras Suri Armenique et contigui Cappadoces colunt, inde Bithynum, hinc Lycium ad mare imperio tenuisse," &c. The strength of the army of Sesostris, as here stated, very nearly coincides with the amount given in the text, on the authority of Diodorus. According to the latter, this army consisted of 600,000 infantry, 24,000 horse, and 27,000 armed chariots; which, as at least three men fought in one chariot, would make a total of 695,000 men, or only 5000 less than the number reported by the priests to Germanicus on the faith of the monuments.

⁴ *Origines, ubi supra.* "It would be in vain," says Sir William Drummond, "to deny to the traditions of ages, to the records of history, and to the authority of monuments, that Sesostris must have been one of the greatest princes that ever lived; while we may fairly confess our doubts of the extent of his conquests, and acknowledge that we cannot ascertain at what period he flourished. The existence of the monarch we may consider as certain; and some of the achievements of the conqueror we may admit to be probable, though we cannot fail to perceive, that the number of his triumphs has been amplified by exaggeration, and the history of his reign crowded with fictions. It is known that the great Ramesses or Ramestes created at least one obelisk, on which he announced himself to be loved and gifted by all the gods of Egypt; but it may be questioned whether he had a right to call himself the master of the whole habitable world. We may believe that Sesostris obtained many victories, and subdued many regions; while we may still avow that we are unable to tell when this mighty monarch reigned, where were the limits of his empire, what humbled nations bowed down before his throne, or what captive kings were yoked to his triumphal car."

⁵ *Essai Général de Tactique*, vol. i. p. 61.

of his achievements, appears to have been a wise prince, a warlike monarch, and a great conqueror;¹ while the victories achieved by the Persians under his command, contrasted with the fatal reverses which they afterwards experienced, may induce superficial observers to imagine that the knowledge of the art declined after the hero's death. No opinion, however, can possibly be more erroneous; except, indeed, it be that which represents the Greek tactics as having been primarily derived from the Persian, to which, as will appear in the sequel, they bore not the slightest resemblance. The qualities of the Persian troops may, perhaps, have deteriorated, and, under the influence of luxury and refinement, the military character of the nation may have declined; but the system of organising armies and making war continued, in a great measure, unchanged: nor, as far as the military art is concerned, would it be easy to discover any material difference between the tactics of Cyrus, who was uniformly victorious, and those of Xerxes, Mardonius, and Darius, who experienced the most disastrous defeats. It should also be remembered, that the former led Asiatics against Asiatics, and that the nations he subdued were among the most effeminate and voluptuous of the ancient world: whilst the latter were called to contend with the Greeks in their best days, when their bodies were robust, their hearts strong, and their discipline admirable; and when their armies were commanded by men fired alike with the love of liberty and of glory, and not only conversant with the science of war, theoretically considered, but eminently skilful in all those resources which neutralize superiority of numbers, and enable handfuls of men to snatch the victory from masses apparently overwhelming and invincible.

The strength of the Persian army consisted in its cavalry, which was always of excellent quality, and capable of achieving great things had it been properly commanded. This was emphatically evinced at the passage of the Granicus, where its gallant conduct attracted the admiration of every officer in the Macedonian army, from the king to the humblest diloche in the ranks.² Notwithstanding the absurd principle upon which it was formed, and the total want of support, owing to the treachery or terror of the Greeks in the pay of Darius, who had been brought forward to sustain it, this cavalry bravely disputed the passage; drove Ptolemy, who commanded the vanguard of the Macedonian army, back into the river; charged the heads of the columns as they successively ascended the bank in order to deploy, with the utmost impetuosity; and maintained the combat until it was attacked by the formidable phalanx in front, and by the light infantry on both flanks, when it was at length forced to retire.³ The Persian infantry had none of the qualities for which the cavalry was distinguished, and seems, in fact, to have been little better than a military mob, without coherence or solidity; while the vast numbers of this arm which were commonly brought into the field impeded the action of the cavalry, which they were incapable of supporting, and served only to create confusion, and supply food for the slaughter, when opposed to disciplined armies com-

manded by men conversant with military combinations. Marathon, Plataea, and Mycale, all bear witness to the truth of this observation. The war-chariots formed another source of disorder and weakness. Their number, like that of the infantry, was excessive; and as these vehicles could only act upon level ground, they were altogether useless and unavailing in a broken country, or against a skilful commander. With regard to the numerical strength of the Persian armies, we have no precise information, and can only form a conjecture from the statements, almost always exaggerated, of the Greek historians as to the numbers actually brought into the field. Xerxes, who had taken by descent a hereditary hatred of the Greeks, invaded Europe, it is said, and entered Greece at the head of an army, which, with its retinue of servants, eunuchs, and women, amounted to upwards of 5,000,000 of souls; a statement which, if true, would imply that the Persian nation had risen *en masse* to overrun the countries of the West. Yet this vast multitude, or rather horde, was arrested in its progress by 300 Spartans at the pass of Thermopylae; and that mountain gorge would have become the scene of its total defeat and destruction, had not a base Trachinian betrayed this devoted band of heroes, and enabled the Persians to attack it at once in the front, the flank, and the rear. At Marathon, Datis and Artaphernes, lieutenants of the Great King, brought into the field 100,000 foot and 10,000 horse,⁴ which were beaten by 10,000 Athenian infantry and 1000 Plataean auxiliaries, commanded by Miltiades. At Plataea, the Persian force, consisting in all of 300,000 men, was again defeated with great loss by a handful of Lacedaemonians and Athenians under Pausanias. And at the battle of Mycale, fought on the same day with that of Plataea (22d September 479 B. C.), 100,000 men, the wrecks of that portion of the army more immediately under the command of Xerxes, which had just returned from the unsuccessful expedition to Greece, were completely overthrown and dispersed by a small body of Greeks, who stormed their entrenched camp, slaughtered several thousands, and carried off an immense booty. On comparing these various numbers, and making due allowance for casualties, it would appear that the Persian monarch must have entered Greece with about 600,000 fighting men; an enormous force numerically considered, but not too great to provoke incredulity, when we reflect on the mode in which the eastern nations have always made war, and further take into account the circumstance, that nearly the whole of one reign and part of another were consumed in making preparations for this ill-fated expedition.

Of the state of the Persian army in the reign of Alexander, Arrian has furnished us with many important particulars, especially in his account of the battle of Arbela, which is the more interesting, as it gives us some insight respecting the Persian tactics under the last Darius. According to this writer, who had consulted the memoirs of Ptolemy, one of Alexander's generals, but who, nevertheless, seems to have possessed the Greek talent for exaggerating numbers, the army which Darius brought into

¹ The achievements of Cyrus, like those of Sesostris, have been so exaggerated by historians, and embellished by fabulists, that almost every grain of truth has to be separated from a bushel of fiction. The *Cyropædia* is merely a philosophical romance, with no more of truth or fact in it than is sufficient to give verisimilitude to the story.

² The Persian cavalry, 30,000 strong, was, on this occasion, commanded by Memnon, who drew it up in a single line of equal extent with that occupied by the Macedonian army on the other bank of the river. The ground on which it was posted sloped gradually towards the bank of the Granicus, which was here steep and difficult, and hence no position could have been chosen more favourable for the effective action of such a force. But its energies were paralysed, or, which comes nearly to the same thing, its full capabilities were never brought into play, in consequence of its linear formation, which admitted only of detached efforts, without *ensemble* or support. (Guischardt, *Mémoires Militaires sur les Grecs et les Romains*, tom. i. p. 251-258. Lyons, 1760.)

³ Guischardt, *ubi supra*.

⁴ The total number of Persians engaged at Marathon was, according to Valerius Maximus (l. v. c. 4), 300,000; according to Justin (l. ii. c. 9), double this amount, or 600,000 men. No attention whatever is due to such extravagant exaggerations.

Army.

the field on this occasion consisted of 1,000,000 infantry, 40,000 cavalry, 200 chariots armed with scythes, and 15 elephants; a statement which appears equally incredible, whether we regard the absolute amount here assigned, or attend to the glaring disproportion between the relative numerical strength of the different arms. Quintus Curtius, who reduces the infantry to 600,000, and raises the cavalry to 145,000, exaggerates at least with method, and thus avoids an objection fatal to the numerical accuracy of the military historian. The disposition of this enormous force, as described by Arrian, shows the incongruous elements of which it was composed. According to the custom of the Persians, the king placed himself in the centre, having around him his relations and the officers of his court, with his ordinary guards, foot and horse, which sometimes amounted to 15,000 men. These he supported by a body of Greeks in his pay, upon whom he placed great reliance, and by other *corps d'élite* furnished by the native army. The Persians, the Susians, and the Candusians composed the left; on the right were the Syrians, the Assyrians, and other nations, subjects or allies of Persia; and the whole was formed into squares or masses of prodigious depth, evidently with the intention of resisting the compact formation of the Macedonian phalanx, of which the Persians had already had woeful experience. These different nations were variously armed, some with missile weapons, others with pikes, hatchets, maces, &c.; and cavalry were stationed in the intervals between the squares. The reserve was composed of those for whom no place could be found in the first line; and being drawn up too close to it, served only to augment the confusion. The infantry of the left was flanked by the main body of the Persian cavalry, and part of that of the Bactrians; together with two corps, one Scythian and the other Bactrian, a little in advance. On the right, the Armenian and the Cappadocian cavalry were posted in a similar manner, though not in equal force. Two hundred armed chariots were drawn up before the left, and fifty before the right of the infantry, while the elephants and fifty more chariots were placed in advance of the centre.¹ Such was the disposition of the army of Darius on this memorable and decisive day. It was doubtless bad in many respects, particularly in the disproportionate crowding of all arms on the centre and left, while the right was left comparatively weak and uncovered; but its greatest defect, inseparable, perhaps, from the heterogeneous composition of the army, consisted in this, that the defeat of any one part of the line was certain to throw the whole into irretrievable disorder, and to end in a complete rout. Still it showed very considerable knowledge of the military art; while the battle which followed, and which was bravely contested, is even yet considered a study for tacticians.

The Greek armies.

From the earliest times, the genius of the Greeks, adventurous and free, inclined them to war. This, at first a consequence of their position, became in time an attribute of the national character, and gave rise to institutions which, in their turn, served to diffuse and confirm the spirit in which they had originated. Divided into a number of petty states, which were separated often by imaginary boundaries, and naturally jealous of one another, Greece was a scene of never-ending contention, and the theatre of almost continual war. New causes of difference,

in the shape of injuries, encroachments, or insults, real or imaginary, were incessantly arising; and as each state was alike proud of itself, suspicious of its neighbours or rivals, and, above all, watchful of its independence, the wrong done, or believed to have been done, was promptly followed by retaliation, which again provoked a repetition of the offence, and thus led ultimately to war. Such a state of things naturally fostered a warlike spirit, and gave birth to military institutions; while the necessity of self-defence, still more than the love of conquest or of glory, rendered it imperative that every citizen capable of bearing arms should be ready to appear in the field at the call of his country. But experience soon taught the important lesson that numbers did not constitute strength, and that a small body of men prepared by early training for the duties of war, and subjected to a system of regular discipline, were capable of contending, on equal terms, with great numerical odds. When this discovery was first made, we have no means of ascertaining precisely; but it is one which must early have occurred to the rulers and governors of small states like those of Greece, the scanty population of which imposed upon them the necessity of devising the best means for rendering its disposable strength effective and available. Hence we find, that one great object of the early statesmen and legislators of this country was to organize a system of physical and moral education adapted to its peculiar position and circumstances; to engraft the military spirit on those institutions which were destined to form the general character of their countrymen; and, amidst the pursuits of peace, to prepare the minds and bodies of their citizens for encountering the fatigues, privations, and perils of war. Nor did their labours prove fruitless or vain; for the institutions thus prepared being suited alike to the genius and condition of the people, soon struck their roots, as it were, into the soil, and ere long produced those fruits which have for ages been the wonder and admiration of mankind. But less perhaps of this wonder and admiration is due to the bravery of the Greeks, eminent as it always was, than to their discipline, organization, and conduct in the field. Among them all the branches of the military art were simultaneously cultivated, and received the most important improvements. Their formation was rendered compact and formidable; combining solidity and the power of resistance, with a mobility which made these qualities available on different points, even in action. Their tactics were singularly adapted to the peculiar character of their troops, and were founded on the most certain principles of the art.² And, in later times, we find strategy recognised and taught as a science in the schools;³ while, in the field, it received, in several respects, a development which no other nation, ancient or modern, has yet been able to surpass. Lastly, we may observe, that until the reign of Philip, the father of Alexander the Great, Greece had no standing army. Her strength consisted in her militia; and to this description of force she was indebted for the imperishable glories of Marathon, Plataea, and Mycale, when the myriads of the Persian invader were successively overthrown. But, from the causes above indicated, and the incessant contests in which the different states were engaged with each other, this militia had acquired the principal characteristics of a regular force, both as regards

¹ Guischart, *Mémoires Militaires sur les Grecs et les Romains*, tom. i. p. 260-61.

² Guibert, in his *Discours Préliminaire*, part second, underrates the tactics of the Greeks. "Je compare les guerres des Grecs," says he, "et la plupart des guerres des anciens, à celles de nos colonies dans l'autre continent. J'y vois cinq ou six mille hommes les uns contre les autres, des champs de bataille étroits, où l'œil du général peut tout embrasser, tout diriger, tout réparer. Un bon major conduiroit aujourd'hui la manœuvre de Leuctre et de Mantinée, comme Epaminondas," p. 82. It will be fortunate for modern armies when their "good majors" are as skilful and as brave as Epaminondas.

³ Guischart, *Mémoires Militaires*, tom. ii. p. 155.

Any. organization and discipline, and consequently was of nearly equal avail against an enemy in the field.

The Spartan any. To the institutions of Lycurgus Sparta was indebted for her military pre-eminence among the states of Greece. To exclude all refinement and luxury, to cultivate the sterner virtues of abstinence and self-denial, to inure the body to hardships and the mind to suffering, to inculcate self-sacrificing patriotism, and to form great characters, appear to have been the principal objects of this iron-hearted legislator; who accordingly laid the foundations of his institutions in a system of primary education, intended and calculated to convert the free male population of the state into a military community, and to develop to the utmost all those physical and moral qualities which render men invincible in war. Nor did the results disappoint the calculations upon which this system had been founded. Trained from their earliest years to suffer the extremes of heat and cold, hunger and thirst, to endure pain with unflinching fortitude, and to despise danger and death; habituated to the most implicit and unquestioning obedience to all placed in authority over them; and continually exercised in running, wrestling, swimming, ball-playing, and martial games of all sorts, as well as in stratagems, surprises, and ambuscades; the Spartan youth, when called to take the field, were prepared at once to enter upon the duties of war with alacrity and vigour, and to regard with indifference all the privations and fatigues of the severest campaign. Nor were their discipline and organization inferior to their military qualities. The Spartan phalanx, which formed the basis of the Macedonian, consisted of eight files in depth.¹ The files were placed at intervals of six feet from one another when disposed in open order; in close order the distance was three feet; in locked order one foot and a half; the intervals being thus diminished one-half at each approximation. The open order was that observed on the march, and in evolutions or manœuvres; the close order was for the attack; and the locked order was that in which an attack was received. The front rank consisted of picked men; the rear rank was also select; while those upon whom least dependence could be placed had their station in the centre, in order to give impetus and momentum to the column by their weight and physical power. The differ-

ent parts of the phalanx were classed according to a regular system, and, in particular, the covering file was matched in quality as nearly as possible with the file in front; so that if the whole or any part of the front rank failed, the vacancies were supplied by the second files, without disordering the line. The arms, offensive and defensive, of the soldier, consisted of a spear or pike, a short sword or dagger, and a shield or buckler of an oval form, which was fastened round the neck and at the left shoulder by means of straps. But latterly Cleomenes changed this clumsy encumbrance for the Macedonian shield, originally invented by the Carians, which was fastened on the left arm by a ring or belt, so as to leave the soldier free to employ both hands in giving force and direction to the pike. The Spartans were also familiar with the most approved evolutions, which they performed with equal celerity and precision. The rear of the phalanx became the front, or the front the rear, by the shortest and simplest operation; while, by redoubling its formation, it became a solid square, bristling on every side with pikes, and, in locked order, wholly impenetrable to attack, except upon broken ground. Rapid changes of front even in the presence of an enemy, refusing or advancing a wing at a critical moment, turning an enemy's flank, and many other manœuvres, which are still considered equally delicate and difficult, were frequently executed with the most complete success by the commanders of these formidable columns. In a word, the Spartans may be regarded as the founders and first improvers of that military system, which attained its perfection under Alexander, and placed the crowns of Asia at his feet.²

The Athenian military force consisted of three classes; The Athenian army. first, the heavy troops, *ὀπλιται*, armed with a spear, a dagger, a cuirass or corslet, and an oval shield, and reserved for the phalanx or main battle; secondly, the light troops, *πυλισταί*, armed with a light spear, a javelin, and a target, and destined for skirmishing, seizing or maintaining positions, and covering the movements of the phalanx; thirdly, irregular troops, *γυμνηταί*, without defensive armour, but provided with missile weapons, such as javelins, bows and arrows, and slings, for harassing an enemy on his march, or performing the duties of light troops in the field.³ The phalanx or main battle consisted entirely

¹ There is some confusion among the ancient writers on the subject of the division of the Spartan force. Thucydides, describing the arrangement and proportions of the Spartan army at Mantinea, informs us that a battalion or *lochos* consisted of four *pentecosties* or companies, a *pentecostie* of four *enomoties* or platoons, and each *enomotie* of 32 men; thus making the whole strength of the battalion 512 men. But he makes no mention of the number of battalions in a regiment, and indeed acknowledges that the subject was obscure, and his information imperfect. According to Xenophon, the Spartan *mora* or regiment consisted of four *lochi*, the *lochos* of two *pentecosties*, and the *pentecostie* of two *enomoties*. The number included in the last denomination is not given; but, if we assume that it consisted of 32 men, as stated by the historian first named, the regiment of Xenophon would amount to 512 men, or 50 more than the battalion of Thucydides. How are these discrepancies to be reconciled? It is scarcely probable that the division of the Spartan force underwent any change in the interval between the time of Thucydides and that of Xenophon; but it is very probable that neither may be correct, considering that the Spartans studiously concealed from the observation of foreigners the internal organization and strength of their armies.

² The Spartan phalanx advanced to meet the enemy's at a regular step, in accord with the cadence of military music, and, even when beaten, generally retired from the field in perfect order, however reduced in number. After battle, every soldier was obliged to produce his shield, as a proof that he had fought, or retired, as a soldier ought to do, bravely and steadily. If he had lost or thrown away his shield he was disgraced for ever; the brand of indelible infamy was fixed upon him. But this was of rare occurrence; for the love of military glory was the only passion which the Spartan people were allowed to cherish; and both education and discipline had combined to eradicate fear from their bosoms. It was a word unknown in their vocabulary. In this singular country all passions merged in one. The Spartan mother and the Spartan wife rejoiced when a son or a husband had fallen honourably in the field of battle, and sometimes refused to recognise as of kindred with themselves such of their relatives as had survived a defeat. The only mourners on account of the disaster at Leuctra were those whose friends and kinsmen had escaped the slaughter of that bloody day.

³ These classes may be considered as analogous, the first to the grenadiers, the second to the light infantry, and the third to the riflemen or sharpshooters of modern armies. Their armour, however, was different at different times; for the Greeks, like the Romans, made several changes in this respect; and hence the apparent discrepancies which we meet with in the accounts of historians. For example, when Arrian mentions the militia of the ancient Greeks, he speaks of the times which preceded the constitution and organization which Philip and Alexander the Great gave to their troops. The oval buckler, larger than common, and the long pike or *sarissa*, were introduced by these sovereigns, and found to add incalculably both to the defensive and offensive power of the phalanx. Some of the Greeks, however, piqued themselves on not adopting the changes of Alexander; but Philipomen at length persuaded the Achæans to lay aside their ancient arms, and assume those of the Macedonians.

Army. of natives of Attica, and was drawn up according to tribes or communities, probably with the view of exciting a generous rivalry in deeds of arms. The light armed troops were partly native and partly foreign; the slingers and archers were wholly foreign. The cavalry, like the heavy-armed infantry, consisted of natives alone, and were of a good description, being remarkably alert, intelligent, and enterprising. Thus composed, the Athenian army was prepared for every species of warfare, and equal to the most arduous achievements. The intelligence, activity, quick perception, and daring spirit of enterprise for which the native of Attica, the Frenchman of Greece, was distinguished, rendered him formidable in desultory warfare, alert in his movements, and prompt in taking advantage of every favourable circumstance; inasmuch that the Athenian light troops foiled, and on some occasions even discomfited, the renowned Spartan phalanx. The Athenian phalanx was less compact than that of Sparta, and, owing to the character of the people, as much perhaps as to its formation, less adapted to receive and repel an attack; but in the charge it was perfectly irresistible. Its onset was terrible, and overthrew all before it. The cause of this must be sought in the difference of national character. The Spartan was chiefly celebrated for his passive, the Athenian for his active courage. Hence the one was powerful in resistance; the other formidable in attack. The Spartan was steady, devoted, and firm; the Athenian bold, enterprising, intelligent, and full of address and dexterity. If the one was less capable of resistance, the other was more ardent and impetuous; their military qualities were as opposite as their natural characters, but both were admirable of their kind; and if it had been possible to combine them together in equal proportions, perfect soldiers might have been formed, and a perfect army organized. The Athenians, we may observe, were the first of the Greeks who advanced upon the enemy at an accelerated pace corresponding to what is now called double-quick time. This innovation was first introduced by Miltiades at Marathon, in order to give increased momentum to the charge which he directed against the Persian masses; and it was consecrated in Athenian tactics by the glorious result of that ever-memorable day.¹

The Macedonian army.

But the very principles which had saved the states of Greece from foreign invasion, and enabled them to maintain their independence, were destined to form the basis of a military establishment, more formidable, because more complete in all its parts, than any which that or other countries had yet produced, and organized for the express purpose of serving as an instrument for subverting Grecian liberty. We allude of course to the Macedonian army in the reigns of Philip and his son Alexander the Great. The founder of this establishment, Philip of Macedonia, was a man of unquestionable talents, of convenient principles, and of boundless ambition. Having improved his natural parts by associating with the scholars, statesmen, and philosophers of his age; and having been initiated into the scientific principles of the art of war under Epaminondas, the most celebrated master of the time; he was early fired with a love of military glory, and a lust of conquest and dominion. But although the brilliant period in the annals of the Greek states was past when Philip made his appearance, and these communities had already begun

Army. to show symptoms of decline, enough of the ancient spirit still remained to convince him, that, without creating new means, and organizing a force different from any which had yet existed, he could never hope to realise his ambitious projects, by rendering himself the master of Greece. The sagacity of Philip was fully on a level with his ambition. He saw that in the rude shepherds and hunters of Macedonia might be found the raw material of an army; that discipline and organization were alone wanting to convert this material into an invincible force; and that to render a military force completely effective, or, in other words, to derive from it the utmost benefit it was capable of affording, it was indispensably necessary to depart from the militia system which had hitherto prevailed, and to start from the principle that no army could be good which was not permanent. He was thus the first who fully comprehended the importance of a standing army, both as regards the efficiency of a military body itself, and also with reference to projects of conquest or ambition; and he may further claim the distinction of having been the first to organize a permanent force. In prosecuting this design he showed a skill, and a knowledge of the principles of military organization, equal to the sagacity evinced by its conception. Adopting the Spartan phalanx as the basis of his system, he gave it greater depth and solidity, so as to render it irresistible in the attack, and impenetrable when drawn up in position. He changed or improved its armour both for offence and defence; and, in particular, introduced the large oblong buckler, and the *sarissa* or Macedonian pike, the most formidable weapon of ancient times. The light-armed troops were also placed on a better footing than they had ever before been among the Greeks, being formed in demi-phalanges, which, without materially lessening their mobility, rendered them capable of combining their efforts in an effective manner with those of the heavy-armed infantry. The equipments, arms, and discipline of his cavalry were in like manner improved, and their organization perfected, with the utmost care and diligence. In a word, all that was excellent in the different Greek systems was combined in the Macedonian; while their defects were avoided, and improvements introduced wherever these seemed to be either expedient or necessary. Such was the general character of the military establishment which Philip created for enabling him to trample on the liberties of Greece, and which Alexander employed in subjugating the world. We shall now speak of its different parts in detail.

The phalanx was composed of files of a certain depth, and of regular combinations of those files. The *lochos* or file was a number of soldiers ranged in line, one behind the other, from the head to the *serre-file* or *ouragos*. The file consisted at different times of different numbers of men, as eight, ten, twelve, and sixteen. Alexander chose the last, because it formed the best proportion relative to the extent and depth of the phalanx; nor did it prevent the archers and slingers, stationed behind, from launching their missiles at the enemy, over the heads of the phalangites. If the phalanx was doubled to form a solid column, or reduced to one half in order to extend its front, the respective depths of 32 and 8 still remained proportional; but if the original depth of the file had been only 8, as in the Spartan phalanx, the latter evolu-

¹ It is very much to be regretted that no military or scientific description has been preserved of the battle of Marathon. The accounts which have reached us, being written by men ignorant of military affairs, are meagre, confused, and unsatisfactory; containing details, indeed, of the numbers engaged, and the amount of the slain, but giving little or no information respecting the combinations and manœuvres which decided the fortune of the day. One thing only is certain,—the victory was the result of consummate generalship on the part of the commander, and of heroic valour on that of the soldier.

tion could not have been performed with safety, because it would have reduced the depth to 4, and thus deprived the formation of its peculiar characteristic of solidity. The preference given to the number 16, therefore, was on account of its divisibility, and its admitting of evolutions consistently with the nature of the phalanx, which could not have been attempted with files composed of any other number, greater or less. The best man was chosen as the head of the file, and named *lochagos* or *protostate*; the second was called *epistate*; the third bore the same name as the first, the fourth the same as the second, and so on to the last; so that each file was composed of *protostates* and *epistates*, ranged alternately from the *lochagos* to the *ouragos*, who was also a picked man.¹ The junction of two or more files was denominated *sylochism*. It was effected by placing the *protostates* and *epistates* of the one exactly opposite the *protostates* and *epistates* of the other; and one man, considered in reference to his juxtaposition with another, was called *parastate*. The junction of all the files formed the phalanx; of which, therefore, the *lochagi*, or heads of files, constituted the front rank, and the remaining *parastates* in alignment, as far as the *ouragi* or *serre-files*, the depth.

The phalanx, thus composed, was divided into two equal parts; one called the right wing or head, and the other the left wing or rear. The point of separation or division was variously denominated the navel, the mouth, and the jointure of the phalanx. And as the principle of this formation was, that every combination should be divisible into two equal parts, so the phalanx, as finally constituted by Alexander, was composed of 16,384 heavy-armed men, the half of which number was considered sufficient for light troops, and the half of that again, or the fourth of 16,384, sufficient for cavalry; while the divisibility into equal parts afforded great facility for executing with precision all manner of evolutions, and extending or diminishing at pleasure the front of an army. The total number of the phalanx being, as already stated, 16,384, and each file consisting of 16 men, it follows that there were in all 1024 files. But each combination of files had its peculiar and appropriate denomination. Two files united formed a *dilochie*, under a *dilochite*; four files, a *tetrarchie*, under a *tetrarch*; two tetrarchies, a *taxiarchie*, under a *taxiarch* or *centurion*; two taxiarchies, a *syntagma* or *xenagie*, under a *syntagmarch* or *xenagos*; two syntagmata, a *pentecosiarchie*, under a *pentecosiarch*; three pentecosiarchies, a *chiliarchie*;

two chiliarchies, a *merarchie* or *telarchie*; and two merarchies, a *phalanx* of 4096 men in 256 files, which was commanded by a general, under the name of *phalangarch*. Again, two phalanges formed a *diphalangarchie*; and two diphalangarchies, a *tetraphalangarchie*, or the grand phalanx, which thus consisted of two wings or diphalangarchies, four phalanges, eight merarchies, 16 chiliarchies, 32 pentecosiarchies, 64 syntagmata, 128 taxiarchies, 256 tetrarchies, 512 dilochies, 1024 files, and 16,384 men. The front might be extended by simply augmenting the distance between the files; the phalanx was closed by lessening the distances between the ranks and the files, and thus diminishing both its front and its depth. Its locked order was called *synapism*, in which the ranks and files were so closely approximated that the soldier could not turn.⁴ In this formation the men at the exterior of the mass held their bucklers before them; the next rank raised their bucklers over the heads of those immediately in front of them; the third rank held their bucklers over the heads of the second, and so on; thus forming a sort of roof, over which the archers in the rear sometimes passed to the front, and which, from the bucklers being joined like the scales of a crocodile, resisted and threw off the heaviest missiles discharged by the enemy. As every thing depended on the steadiness of the heads of files and their *epistates* of the second rank, both were *gens d'élite* or picked men. When the phalanx was closed for action, each man occupied only three feet of ground in rank and file. The pikes or *sarissæ* were 24 feet in length, 6 feet being behind and 18 feet before the grasp; consequently (as the ranks were three feet separate), the second rank advanced the pike 15 feet, the third 12, the fourth 9, the fifth 6, and the sixth 3 feet; thus presenting an array of points such as never bristled along the front of any other military mass or column. The soldiers of the other ranks, as they could not employ their pikes, pushed on those before them, and, by their weight, served to augment the violence of the shock.⁵ In this case every thing depended on the *serre-files* or *ouragi*, who were the keys of the phalanx, and, like the *lochagi*, picked men. Such was the Macedonian phalanx,⁶ which was destined to conquer the world, and to be, in its turn, conquered by the world's conquerors. It yielded to superior tactics and greater mobility.

The light-armed infantry were drawn up in different ways, according to the nature of the ground and the dis-

¹ Some authors designate a file *stichos*, others *decuria*. They who apply the latter epithet seem to suppose that it consisted of ten men, which is not true as respects the Macedonian file. We have followed, in the text, the nomenclature of Arrian, whose authority on this subject is decisive. With regard to the term *enomotie*, which has so much puzzled commentators, we have already shown that it means something different from a file, or part of a file. It was a term peculiar to the military system of Sparta, whence it passed into the other systems of Greece, including the Macedonian; but no data have been given from which its precise import can be ascertained.

² The *syntagma* or *xenagie* had four supernumerary men; a standard-bearer, an officer who marched behind and performed the duty of our major, an adjutant, and a crier to repeat the orders. This section, ranged in order of battle, formed a perfect square. (Arrian's *Tactics*.)

³ The *pentecosiarchie* of the Macedonians answered to the *lochos* of the Spartans. This must be kept in mind in the perusal of Thucydides and Xenophon, otherwise both will be unintelligible.

⁴ It was to this locked order that Epaminondas was indebted for the victories which he gained over the Lacedæmonians at Leuctra and at Mantinea. The Theban army was formed in columns of attack, upon a front considerably less than the depth. The shock, therefore, proved too much for the Spartan phalanx, which was only eight deep. Xenophon compares it to that of a heavy vessel striking a light one amidships with her bow, and dashing her to pieces by the collision.

⁵ The loss of men in the day of battle, or the necessity of sending out detachments, made no change in the form and disposition of the phalanx. The sections were always kept up to their full complement of ranks and files. The effective diminution fell, not upon the ranks and files, but upon the number of the sections, which were retrenched in proportion as they filled up the void in the phalanx.

⁶ The Macedonian phalanx, says Arrian, was as formidable in appearance as it was in reality; and Paulus Æmilius confesses, that, when he saw, for the first time, this imposing mass, with its front bristling with the terrible *sarissæ*, he was struck with consternation. Guischartt alleges that it was "plus terrible à l'aspect que dans l'effet;" and adds that Paulus "ne laissa pas que de la battre avec ses Romains épars et distribués en plusieurs pelotons." But if Alexander had commanded it, the Roman would have told a different tale. Guischartt has himself demonstrated that the loss of the battle of Cyncephale was mainly, if not exclusively, owing to the stupidity of Philip in committing the phalanx upon broken ground, where its flanks were uncovered, and the principal advantages of its formation lost.

Army. position of the enemy; sometimes before the phalanx, sometimes behind it, sometimes on both wings, sometimes only on one. Their formation was in all respects similar to that of the phalanx, and their files, eight deep, were combined upon analogous principles. The Macedonian cavalry was of various descriptions, as *kataphracti*, light horse, and *acrobolista*. The *kataphracti* or cuirassiers were completely covered with defensive armour; the man with a cuirass and cuisses of iron scales, the horse with a frontlet and mail. Their offensive arm was the Macedonian pike. The light cavalry, unencumbered with heavy armour, carried lances and missile weapons. The *acrobolista* had no lances, and, like the Armenian or Turkish cavalry, used only the bow and arrow. They were a species of Cossacks or irregular horse, and performed the duties of such. The usual formation of the regular cavalry for attack was the cuneiform, which had been introduced by Philip, from an idea that it was the order best calculated to pierce an enemy's line; but they were sometimes drawn up in squares, sometimes in the form of a rhombus, and sometimes also in a line.

The numerical strength of the Macedonian, like that of other ancient armies, can only be conjectured from the numbers actually brought into the field. In the time of Philip it probably never exceeded a grand phalanx, with its proportional complements of light troops and cavalry, 28,603 in all, and a few thousands of auxiliary troops. At the passage of the Granicus, Alexander's army consisted of above 30,000 infantry and 5000 cavalry; from which we may conclude that it was composed of one grand phalanx, with its proportional complements of light troops and cavalry, and about 6000 auxiliaries. But it was afterwards powerfully reinforced; for Alexander paid great attention to recruiting, especially in Greece, and had always generals detached from the army for the purpose of raising new levies in that country. Accordingly we find that, at the battle of Arbela, the Macedonian army consisted of two grand phalanges, or 32,768 heavy armed infantry, two corps of *peltasta*,¹ each 8186 strong, and 4096 cavalry, including the Thessalian horse, besides several thousand auxiliaries, chiefly irregular troops; thus making a grand total, including auxiliaries, of at least 60,000 fighting men, or 54,000 regular and 6000 irregular troops.

It has been supposed by some that this army, like that of Carthage, was heterogeneous in its composition; that men of all nations were to be found in its ranks; and that a stern, unrelaxing discipline constituted the only *vinculum* or tie by which the naturally discordant mass was held together. There cannot possibly be a greater mistake. The Macedonians, it is true, formed but the nucleus, as it were, of the army; and, both in the reigns of Philip and Alexander, recruits were obtained in considerable numbers from the neighbouring states of Greece. But whatever shades of difference might have been produced by local circumstances and diversity of institutions, the inhabitants of all these states were essentially one and the same people; identical in origin, distinguished by like peculiarities physical and moral, and possessing a general national character. In what respects, then, can the Macedonian army be considered heterogeneous? None but Greeks were admitted into the ranks of the phalanx, or those of the light infantry and cavalry; no barbarians were received even as auxiliaries. It was composed exclusively of people of the same country and the same general character, who all spoke dialects of the same language, shared a common

temperament, and were distinguished by their physical configuration, no less than by their intellectual and moral attributes, from the inhabitants of the surrounding nations. If ever there was an army, therefore, which discipline could render more completely homogeneous than another, it was that of Macedon during the reigns of Philip and Alexander; nor do we know of any modern army to which this epithet can with equal justice be applied. The British army is composed of English, Scotch, Irish, Welch, and Highlanders; the French, of Bretons, Normans, Gascons, Alsatians, Savoyards, and many other tribes; the Austrian, of Hungarians, Bohemians, Transylvanians, Croatians, and Germans; the Prussian, of Silesians, Saxons, Poles, Pomeranians, and Brandenburgians; and the Russian, of Muscovites, Poles, Sclavonians, Tartars, Circassians, Armenians, and innumerable other races; yet all these are considered national armies, and have each, in fact, a national character. But if such assemblages are to be regarded as homogeneous, we know not upon what principle the Macedonian army, composed exclusively of Greeks, can possibly be viewed in a different light, or supposed to have had no other bond of union than what was created by discipline alone.

The only other Greek armies which seem to require notice are those of the Thebans and of the Achæan League. The Theban army, like Theban independence, may be said to have been created by Epaminondas, and to have expired when that great captain fell in the arms of victory upon the field of Mantinea. Still it is a striking example of what genius and discipline may effect, even when called to work upon the most unpromising materials. Epaminondas found it a rabble, and he left it the most formidable military force which Greece had ever yet known. He gave it that organization which rendered it victorious at Leuctra and Mantinea, and which shook to the very foundation the power of the Lacedæmonians. Aware that the Spartan phalanx was invincible by any similar formation, and that he could only hope to prevail by bringing against it a greater concentration of physical energy, he organized the Theban army in columns upon a front less than their depth, so as to enable him to direct the whole or any part against a given point of the enemy's line, and to bear it down by an irresistible superiority of force; and he adapted his tactics to this organization. At the battle of Leuctra, accordingly, Epaminondas, observing the Lacedæmonians advance their two wings before the centre, so as to form the order which the Greeks called the half-moon, instantly attacked the centre of one of these wings, and, having penetrated it, soon succeeded in throwing the whole into irretrievable confusion. Here the onset was made by one wing in column against another in comparatively open formation; and hence the Theban order of attack became the oblique, which is erroneously supposed to be a discovery of modern times. At Mantinea the Lacedæmonians carefully avoided the blunder for which they had paid so dear at Leuctra, and kept their forces more concentrated; but Epaminondas, forming the whole of his infantry in a single column, precipitated it upon a part of the enemy's line, overthrew it, and thus decided the fortune of the day. The Theban army, immediately after the battle of Leuctra, is said to have amounted to 50,000 men. This, however, is probably an exaggeration.—With regard to the army of the Achæan League, it continued insignificant for

¹ For an able and learned account of the *peltasta*, who sometimes formed considerable bodies, particularly in the armies of Alexander and his successors, and whose reputation almost equalled that of the phalanx itself, see Guischart's note to his Translation of Arrian's *Tactics*, in the second volume of his *Mémoires Militaires*, p. 177.

the greater part of a century after that celebrated confederacy was entered into. Aratus was the first who placed it on a respectable footing, and taught it to conquer at Caphyæ; and he was succeeded by Philopœmen, incomparably the most scientific commander of ancient times, who completed its organization, and led it to victory at the second battle of Mantinea, where the Spartans, under Machanidas, were completely defeated, and the tyrant himself slain by the hand of the Achæan chief. This victory was exclusively owing to the superior tactics and dispositions of Philopœmen; who, instructed by the successes of the Romans, had contrived, with infinite skill, to combine, in the formation and arrangement of his troops, the advantages of the legionary order with those of the phalanx. The invaluable fragment of Polybius, containing a description of the battle of Mantinea, gives no account of the numbers engaged. We learn, however, that Philopœmen having assembled the troops of the League, spent eight months in perfecting their discipline and organization before he ventured to commit them in the field against so experienced and warlike an enemy as the Spartans.¹ An army is a piece of mechanism which only acts effectively when all the parts are combined and adjoined together so as to insure the most complete concert and unity of operation; and discipline is the mean by which this important result is produced. It is in fact the art of creating a new power; and so great is its efficacy that it sometimes develops in men those qualities which it only professes to direct and regulate.

This remark is strikingly exemplified in the history of the Carthaginian army. That army was almost entirely composed of mercenaries, or at least of levies drawn from countries differing in language, in manners, in customs, and in character. In its ranks were to be found Africans, Spaniards, Gauls, Boians, Insubrians, Etruscans, and various other races; yet such are the fusing effects of discipline, that this apparently heterogeneous mass vanquished the Romans on the Ticino; overthrew their legions in three pitched battles, at Trebia, Thrasymenus, and Cannæ; and, if Hannibal had known how to profit by victory, might have planted the Carthaginian standards amidst the ruins of Rome. The advantages of a truly national army are great, especially in reverses: it may be beaten, but cannot easily be destroyed: and even its disasters may teach it that experience which will ultimately conduct it to victory; as happened to the Romans in ancient, and to the Russians under Peter the Great, in modern times. But, on the other hand, many instances might be produced to show, that the most effective armies may be organized out of the most discordant and unpromising materials; and that, while nothing can supply the want of discipline, discipline can almost atone for and remedy every thing. With an army composed as we have already described, Hannibal maintained, during sixteen years, the war against the Romans in Italy, without sustaining any serious reverse; nor did he withdraw, until his presence was rendered necessary for the defence of his country; which the successive defeats of the other Carthaginian commanders, both by sea and land, had uncovered, and exposed in its turn to the attacks of an invader. Finally, he was vanquished at Zama from the same cause which had rendered him so often victorious—namely, superiority of discipline: for although his military genius never shone forth more transcendently than in his last field, and although his dispositions were in all respects worthy of his high

reputation, yet the raw and undisciplined levies which formed the strength, or rather the weakness, of his army, were in no condition to contend with the Roman legions, whom sixteen years of incessant warfare had improved both in discipline and experience.² In reflecting upon the issue of this decisive conflict, which terminated the long and sanguinary struggle between the rival republics of Carthage and Rome; and, above all, in considering the precarious nature of that power which is built on the uncertain foundation of military glory; the mind insensibly passes from the contemplation of the fate of the Carthaginian chief to that of a still greater commander, which in some measure resembles it—from the days when these warlike republics contended for the empire of the world, to our own times, when, in a new field of Zama, another Scipio conquered another Hannibal.

With regard to the numerical strength of the Carthaginian army, it appears to have varied at different times. The force with which Xantippus defeated Regulus, and made him prisoner, did not probably exceed 20,000 men; and we learn incidentally that the heavy-armed infantry which the Lacedæmonian had formed in phalanx, conformably to the tactics of his country, amounted to between 8000 and 9000 men, and were all native troops. But when the Carthaginians afterwards invaded Spain, they recruited their armies from the population of the country, and that of the neighbouring provinces of Gaul, until the total numerical strength of these must have considerably exceeded 100,000 men. Livy assures us that Hannibal set out on his expedition to Italy at the head of 100,000 foot and 10,000 horse, but that he lost 30,000 men in crossing the Alps; so that, according to the Roman historian, he must have entered Italy with about 80,000 men. But the numbers actually brought into the field completely disprove this statement: for it is admitted by Livy himself that, at Trebia, Hannibal had only 30,000 infantry and 10,000 cavalry, and that he vanquished at Cannæ with 40,000 foot and 10,000 horse. We shall be nearer the truth, therefore, if we suppose that the invasion of Italy was undertaken with little more than half the number of troops mentioned by Livy; and that the losses sustained in crossing the Alps were, in a great measure, repaired by the recruits which Hannibal drew from the Boians, Insubrians, and his other allies; a supposition which seems completely borne out by the authority of Polybius. But when the Carthaginian general set out from New Carthage for Italy he left two other armies in Spain; and, if we assume these to have been each about 30,000 strong, while the force under his own command exceeded 50,000, it will follow that, at this time, the Carthaginians had considerably more than 100,000 men of all arms in the field.—Let us now attend to the composition and organization of that strictly national force with which these well-disciplined condottieri were called to contend, and by which, after sustaining many reverses, they were ultimately overthrown.

The army of Rome, in the days of her conquests, was perhaps the most perfect, certainly the most formidable, which the world had yet seen; and the superiority which it ultimately obtained over the military force of every nation to which it was opposed, seems to have been exclusively owing to the pre-eminent excellence of its discipline and organization. “Nulla enim alia re videmus populum Romanum orbem subegisse terrarum,” says Vegetius, “nisi armorum exercitio, disciplina castrorum, usuque militiæ. Quid enim adversus Gallorum multitudinem paucitas Ro-

¹ See Guischart's commentary on this battle, *Mémoires Militaires*, tom. i. p. 177.

² We must again refer to Guischart, tom. i. p. 216, more especially as this very able military commentator exposes the misrepresentations of Folard, who seems to have been alike incapable of comprehending the narrative of Polybius, or the dispositions of Hannibal.

Army.

mana valuisset? Quid adversus Germanorum proceritatem brevis potuisset audere? Hispanos quidem non tantum numero, sed etiam viribus corporum nostris præstitisse, manifestum est. Afrorum dolis atque divitiis semper impares fuimus. Græcorum artibus prudentiaque nos vinci, nemo unquam dubitavit. Sed adversus omnia profuit tyronem solertem eligere, jus (ut ita dixerim) armorum docere, quotidiano exercitio roborare, quæcunque evenire in acie, atque in præliis possint, omnia in campestri meditatione prænoscere, severe in desides vindicare. Scientia enim rei bellicæ, dimicandi nutrit audaciam. Nemo facere metuit, quod se bene didicisse confidit. Etenim in certamine bellorum, exercitata paucitas ad victoriam promptior est: rudis et indocta multitudo, exposita semper ad cædem.¹ The military age was seventeen; and, when the exigencies of the state required it, every citizen, from seventeen to forty-six, or even fifty, was obliged to enrol himself as a soldier. Except on pressing emergencies, however, the more youthful part of the population was preferred, as that which could be most effectually trained to the exercises and formed to the discipline of war.² These were of the most severe description, and had for their object not merely to instruct the soldier in the use of arms, in marching, and in evolutions, but to develope and improve to the utmost his physical powers; to inure him to labour, fatigue, and hardships of all kinds; to qualify him for surmounting with ease the various obstacles and difficulties incident to a state of active warfare; to give precision and rapidity to his movements; and, above all, to create that confidence in himself, and that unbounded reliance upon the efficacy of order, subordination, and combined action, which nourish audacity, yet temper it with coolness and steadiness. Besides the use of arms, of which we shall hereafter speak, the young soldier was, accordingly, trained to the exercises of running, leaping, vaulting, wrestling, and swimming, armed as well as unarmed: he was required to perform long and frequent marches, at the rate of four miles an hour, carrying a load of sixty pounds weight: he was carefully instructed in the use of the tools necessary for throwing up all manner of field-works, particularly fortifying the camp: and, even after he had been found qualified to join the legion, he was constantly employed, while in camp, either in the practice of these manly exercises, or in acquiring greater dexterity and precision in the use of his weapons. The Roman soldier knew no intervals of idleness, and was not allowed time to indulge in dissipation. The camp was his home: war was his business: its exercises formed his amusement: its success constituted his glory. In the legion to which he belonged were concentrated all his hopes, all his thoughts, and all his affections.

In raising troops to constitute the legions, the method adopted by the Romans was that which they denominated *election*; because the magistrates chose from the different

tribes the citizens whom they considered best fitted for the military service. The consul or the prætor assembled in the Campus Martius, or in the Capitol, all the citizens, who were bound to concur in the formation of the legions, raised every year, conformably to a decree of the senate; and this obligation included all Romans within the age above specified, who had not served twenty campaigns as foot soldiers, or ten campaigns as horsemen or knights; with the exception, however, of the lowest class, which was exempted from military service on account of its poverty. The number of legions commonly raised was four;³ and the first step consisted in the appointment, either by the people or the consuls, of six tribunes to each legion. The conscripts being classed according to their tribes, the magistrate, charged with the levies, then elected four successively from each tribe. Of every four thus designed the tribunes of each legion in their turn chose one, whose name was immediately inscribed in its muster roll; and this operation, which established a perfect equality in the composition of the legions, was repeated until they had received their proper complement of men. On the termination of the election each legionary individually took the *sacramentum* or military oath; swearing to be obedient to his general, and to execute his commands in all things to the utmost of his power and ability. Nor was this a vain ceremony; for the Romans, trained up in the fear of the gods, had a peculiar reverence for the sanctity of an oath. Roman citizens alone were admitted into the legions, until the time when the civil wars led to the subversion of the republic, and the violation of all established rules. Those, however, who had completed the prescribed period of service, or had attained their fiftieth year, were no longer obliged to take arms in defence of the state, and were only liable to be called out in the event of the city being threatened with some imminent danger. But these brave veterans, habituated to a military life, frequently inscribed themselves as volunteers, and thus served both as models and examples to the young legionaries, who seldom failed to profit by their experience, and generally showed an ambition to come up to their standard.

As soon as the military oath had been administered, the tribunes dismissed the legionaries, having first indicated the time and place where they were afterwards to assemble in order to be embodied. At the general muster, on the day fixed for this purpose, the youngest and poorest in each legion were selected as *velites*; the next in order were chosen as *hastati*; the class immediately above constituted the *principes*; and the *triarii* were formed of the oldest and richest citizens elected to serve in the legions; the different classes being thus arranged according to their arms, their fortune, and their age. The legion was commonly composed of 1200 *hastati*, 1200 *principes*, 1200 *velites*, 600 *triarii*, and 300 cavalry or knights; thus making its total

¹ Vegetius, *De Re Militari*, l. i. c. 1. Raphengii, 1607.

² "Adolescentes legendi sunt, sicut ait Sallustius: nam primum juvenus, simul ac belli patiens erat, in castris per laboris usum militiam disciebat. Melius enim est, ut exercitatus juvenis causetur ætatem nondum advenisse pugnandi, quam debeat præterisse. (Vegetius, l. i. c. 4.)

³ A consular army consisted of two legions, and of a certain number of troops furnished by the *socii* or allies of Rome. The infantry of the allies, according to Polybius, did not surpass in number the legionary infantry in a consular army, but their cavalry was double the number of the knights. The fifth part of their infantry and the third part of their cavalry formed a *corps d'élite*, called *extraordinary* or *elect*, under the immediate orders of the consul; while the remainder of the social troops were divided into two corps, one called the right and the other the left wing. Hence a consular army consisted, in Roman troops, of 6000 legionaries of the line, 2400 *velites*, and 600 knights; in social troops, of 6700 infantry of the wings, 1700 extraordinary infantry, 800 cavalry of the wings, and 400 extraordinary cavalry; making a total of 18,600 men. But when Rome had a difficult war to carry on, two consular armies were raised, and both the consuls took the field; which, in fact, happened almost every year. Lastly, when urgent circumstances required it, the consular armies were doubled and united in order to contend with a formidable enemy. Thus the Romans assembled at Cannæ four consular armies, or nearly 80,000 men, to try the fortune of arms against Hannibal; and, in the heat of the second Punic war, they raised as many as twenty-three legions, or considerably more than 100,000 men. "Alors," says Rogniat, "les armées se multiplièrent en raison de ce grand nombre de légions; les deux consuls choisissaient celles qui leur convenaient, et le commandement des autres était confié à des préteurs, à des proconsuls, et à des propréteurs." (*Considérations sur l'Art de la Guerre*, p. 29, 30.)

strength 4500 men. The tribunes, in concert with the centurions, divided the three classes of *hastati*, *principes*, *triarii*, into ten *ranks*, *manipules*, or *companies* each: the *velites* were distributed in equal portions among these thirty manipules: and the cavalry were divided into ten parts, called *turmæ* or troops. Such is the account given by Polybius, who, doubtless, describes the legion as it was constituted in his time.

The *hastati*, so called from the *hasta* or spear with which they were originally armed, commonly formed the first line in the order of battle; the *principes* were placed in the second line; whilst the oldest and best legionaries, classed under the name of *triarii*, constituted a reserve in the third line. The *triarii* were originally the only troops armed with the *pilum*, a species of heavy javelin, which will be described hereafter; and hence they are sometimes designated by the ancient historians under the name of *pilani*, while the *principes* and *hastati* are denominated *antepilani*: but these denominations necessarily ceased when the three lines adopted the same arms. The *velites*, distributed among the manipules, as already mentioned, were the light infantry of the legion, of which they formed about a fourth part; and known at first under the name of *rorarii* and *accensi*, they were afterwards called *velites*, and ultimately *ferentarii*. But the reader must be careful not to confound these light troops, which always formed part of the legion, with the cohorts of archers and slingers attached to the armies in the time of Cæsar; since the latter were merely auxiliary troops, and had nothing whatsoever in common with the legion. The legionary cavalry, composed of a body of 300 horse, denominated the *ala* or wing, and forming about the twentieth part of the legion, was divided into ten *turmæ*, of thirty horsemen each; while the *turma* was again subdivided into three *decuriæ*, of ten cavaliers each; and the whole was chosen from among the *equites* or knights, who formed one of the first orders at Rome.

When the classification had been completed, the tribunes of each legion proceeded to the appointment of centurions. They commenced by naming ten *first centurions* in each class, except that of the *velites*; after which they proceeded to the nomination of an equal number of *second centurions*; and the legionary infantry being divided into ten manipules of *hastati*, ten of *principes*, and ten of *triarii*, among which the *velites* were equally distributed, they assigned a first and a second centurion to each manipule; the first commanding the right, and the second the left of the manipule, under the orders of the first, whose place he supplied in the case of absence or death. The tribunes also named three decurions in each of the ten *turmæ* of horse; but the decurion first named had the sole command, and the two others were only his lieutenants. Thus a legion had sixty centurions or officers of infantry, thirty decurions or officers of cavalry, and six tribunes or officers of the staff. The tribunes commanded the legion each in his turn during two months; and this continued to be the practice until the epoch of the civil wars, when, for reasons sufficiently obvious, the command was intrusted to a *legatus* or lieutenant-general. The tribunes on service superintended the establishment and fortification of the camp, disposed the guards necessary for insuring its safety, transmitted to the centurions the orders of the general, took care that these were duly executed, and attended to the discipline and exercise of the troops; whilst the others were placed by the *legatus* or the consul at the head of detachments, reconnoissances, or foraging parties, and intrusted with

the command of posts, or employed on particular missions, for raising contributions of money, provisions, clothing, and arms in the conquered countries; in a word, they were staff officers disposable for all kinds of service. The centurions were divided into several grades. Besides the distinction of first and second, established with reference to the manipule, they took precedence among themselves according to the relative distribution of the classes to which they belonged; so that a centurion of the *triarii* ranked above a centurion of the *principes*, and a centurion of the *principes* above a centurion of the *hastati*. And the first centurion of each class, that is, the *primi hastati centurio*, the *primus principes*, and the *primipilus* or *primipili centurio*, commanded the whole of his class, or one of the lines of battle of the legion; which accounts for the high consideration that these three superior officers enjoyed among the Romans. They were commonly admitted to the council of the general, along with the tribunes; and the *primipilus*, the chief of all the centurions, by reason of the pre-eminence of his class, commanded the whole legion in the absence of the tribunes. Further, each centurion and decurion chose for himself, or received from the tribunes, a sub-officer to aid him in the details of the service; and we learn from Vegetius, that there was moreover placed at the head of each squad or tent of ten soldiers a *decanus* or corporal, who performed the duties of that humble rank.¹

Such was the constitution of the legion in the time of Polybius, the friend and contemporary of the second Scipio. But an important, we might almost say a radical, change in its organization was afterwards introduced; a change which has been ascribed to Marius, and which appears to have commenced at the epoch of the wars against Jugurtha. The legions then ceased to be ranged in lines of *hastati*, *principes*, and *triarii*; for the last order of battle, according to the ancient formation, of which historians give any account, is that of Metellus against Jugurtha, as described by Sallust. From this period we always find the legions ranged by cohorts, without distinction of classes, in a double or a triple line. The classification which had been originally occasioned by difference of arms no longer served any purpose, after all the troops of the line were armed in the same manner; except to divide the legion into three large bodies of about 1600 each, including the *velites*, which formed part of them. But experience proving that such bodies were too numerous to be easily directed by a single commander, and too heavy and lumbering for the exigencies of Roman tactics, their place was supplied by a number of smaller and more manageable bodies, and the legion, consequently, divided into ten cohorts, each consisting of three manipules, under six officers, who preserved their denomination and command in their respective manipules. The force of the cohort was raised from 400 to 600 men, thus making the total strength of the legionary infantry 6000; and the first cohort was composed of picked men, who were intrusted with the eagle, under the orders of the *primipilus*. A new order of battle was also adopted, the legions being commonly drawn up in two lines of five cohorts each, leaving small intervals between each cohort. But Cæsar, justly considering these *lacunæ* dangerous, and thinking the new formation deficient in solidity, preferred a continuous alignment, and recurred to the ancient formation in three lines, placing four cohorts of each legion in the first, three in the second, and three in the third line.

¹ Erant decani, decem militibus præpositi, qui nunc caput contubernii vocantur. (Vegetius, *De Re Militari*, l. ii. c. 8. See also Rogniat, *Considérations sur l'Art de la Guerre*, p. 7, et seqq. Paris, 1820.)

Army.

The civil troubles which led to the subversion of the republic produced still further changes. For a time the legionary cavalry entirely disappeared, and their place was supplied by auxiliary horse: strangers, and even slaves, were admitted into the legions, the force of which varied from 4000 to 6000 men: and the social troops disappeared by the admission of all the natives of Italy to the rank of citizens. In the imperial times, as we learn from Vegetius, the legion consisted of 6100 infantry and 726 cavalry. The decimal division of the infantry into cohorts remained the same. "The cavalry," says Gibbon, speaking of that attached to an imperial legion, "without which the force of the legion would have remained imperfect, was divided into ten troops or squadrons; the first, as the companion of the first cohort, consisted of 132 men, whilst each of the other nine amounted only to 66: the entire establishment formed a regiment, if we may use the modern expression, of 726 horse, naturally connected with its respective legion, but occasionally separated to act in the line; and to compose a part of the wings of an army."¹ This is at once clear and precise. But it has, nevertheless, been supposed, and not without reason, that when the legionary cavalry was augmented, the number of *turmæ* was proportionally increased; and that no such inequality as that mentioned by Gibbon existed between the *turma* attending the first cohort and those attached to the others. In fact the *turma* or squadron, at this period, consisted of 32, or, including the decurion, 33 men; and as the total number of cavalry belonging to the imperial legion was 726, it follows that there were in all twenty-two *turmæ*, of which four, or 132 men, were attached to the first cohort, and two, or 66 men, to each of the remaining nine. The result in both cases, however, is the same; while Gibbon's statement may perhaps be preferred as proceeding upon the more ancient division.²

The armour of the Roman infantry consisted of the demi-cylindrical buckler or shield, the cuirass or pectoral, the casque or helmet, and the ocrea or greave. The demi-cylindrical buckler or shield, four feet in length by two feet and a half in breadth, and constructed in the form of a tile, was composed of two or three pieces of timber fashioned and secured together in the manner of staves, covered with leather, strengthened at each extremity by a band

of iron, and provided in the middle with an *umbo* or boss of metal, for the purpose of turning aside the missiles and pikes of the enemy. The casque, helmet, or head-piece of brass was variously formed, but generally fitted with projections at the base for protecting the neck and shoulders, and attached under the chin by *mentonnières*, covered with scales of brass. The cuirass or pectoral was a hollow plate of brass about a foot square, adapted to the form of the chest, and fastened with thongs of leather protected by metallic scales; but the centurions and foremost legionaries rendered themselves still more impenetrable to the steel of the enemy by using chain armour covered with brass scales. Lastly, the ocrea was a species of boot or greave, fortified with iron, and worn on the right leg, which the soldier advanced in striking his adversary.³ Their offensive arms were the javelin, the *pilum* or heavy dart, the pike, and the sword. The sword called Spanish⁴ was common to all the infantry of the legion. It had a short broad blade of excellent temper, which served either to cut or thrust,⁵ and was worn by the soldier on the right thigh. The javelin belonged exclusively to the light infantry or *velites*. It was a species of dart, with a round shaft about three feet in length and an inch in diameter, shod at one extremity with iron about four inches in length, and tapering to a very sharp point. In the day of battle the light troops had each seven of these weapons, which they launched at the enemy with much dexterity and precision. When it became necessary to have recourse to the sword before the whole or any part of the javelins were thrown, the soldier passed them to his left hand, which remained free in consequence of the buckler being attached to the left arm. The light troops were also provided with bows and arrows, and slings, which they used in skirmishing at a distance. The *pilum* or heavy dart, intended to serve principally as a missile, was originally borne by the *triarii* alone, whence the name of *pilani*, but was afterwards appropriated to the *hastati* and the *principes*. Its shaft was of such a thickness as to be easily grasped by the hand;⁶ and the weapon, including both wood and iron, was about seven feet in length. The iron, however, was of the same length as the wood, extending to the middle of the shaft, which was firmly inserted in it, and made fast by nails driven transversely; and it was of a square form, of an inch

¹ *Decline and Fall of the Roman Empire*, vol. i. chap. iii. p. 13, 14, 8vo ed.

² "The *turma* of the Romans," says the Count von Bismarck, "had, according to Vegetius, eight files and four ranks; ten *turmæ* formed a legion; the distances between the *turmæ* were equal to their front." (*Cavalry Tactics*, p. 273, Engl. transl.) It would be curious to learn in what edition of Vegetius the Count discovered that the *turma* of the Romans had eight files and four ranks, and that ten *turmæ* formed a legion, or brigade of infantry and cavalry, united in very unequal proportions. Unless the Count has found out something to which the Romans themselves were strangers, he must have fancied that, in describing the formation of the infantry of the legion, Vegetius was speaking of the cavalry.

³ When the Roman soldiers threw their *pila* or heavy darts, they had the left leg foremost; but when they engaged in close combat with the sword, they were taught to advance the right leg, which was accordingly protected by the iron-covered greave or boot above mentioned. (Vegetius, lib. ii. cap. 15 and 16; Justus Lipsius, lib. iii. dial. 2, *De Mil. Rom.*; Guischart, tom. ii. p. 160.)

⁴ The *gladius Hispanicus* is thus described by Polybius:—"ἄμα δὲ τῶν θυρῶν μαχαίραν, ταυτηνὴν δὲ περὶ τὸν δεξιὸν φέρει μῆρον. Καλοῦσι δὲ αὐτὴν ἱβηρικὴν· ἔχει δὲ αὐτὴ κεντήρια διαφόρον, καὶ καταφορὰν ἐξ αὐφὸν τῶν μῆρον βίαιον, διὰ τὸ τὸν ἐβηρικὸν αὐτῆς ἰσχυρὸν καὶ μόνιμον εἶναι." The name of this weapon sufficiently indicates its origin. An unknown writer, quoted by Suidas, says that "the Celtiberians excelled all others in the manufacture of swords, strongly-pointed and double-edged; wherefore the Romans, laying aside the swords which had been in use among their ancestors, replaced them, in the time of Hannibal, with the Spanish blades. But (he adds) although they assumed the form, they were unable to imitate the temper of the steel and the beauty of the workmanship." Josephus says that, in his time, the Romans had two swords—one of considerable length, which hung at the left side, and another about a foot long, which they carried on the right thigh; in other words, a sword and a dirk, like the Scottish Highlanders. Similar changes in the arms of the soldiery may be remarked every century.

⁵ The Romans invariably gave the point, and derided the practice of those who depended on the cut rather than on the thrust. "Præterea non *cæsim*," says Vegetius, "sed *punctim* ferire discabant. Nam *cæsim* pugnantibus non solum facile vicere, sed etiam derisere Romani. Cæsa enim quovis impetu veniat, non frequenter interficit; cum et armis vitalia defendantur, et ossibus. At contra puncta, duas uncias adacta, mortalis est. Deinde dum cæsa infertur, brachium dextrum latusque nudatur. Puncta autem tecto corpore infertur, et adversarium sauciat ante quam videatur." (*De Re Militari*, l. i. c. 12.) This, we believe, is still accounted sound doctrine of fence.

⁶ This seems to be the meaning of the Greek word *παλαιστιαίος*, applied by Polybius to the shaft or helve of the *pilum*; for, taking it in its ordinary acceptation, the shaft of the *pilum* would have been four inches in diameter; a size which, considering the length of the weapon, and the weight of its iron, would have rendered it an impracticable arm. Dionysius of Halicarnassus confirms this opinion by describing the *pila* as *χειροσπληνῆ* or weapons that completely fill the hand. Polybius compares this formidable arm of offence to a boar-spear.

Any. and a half at its greatest thickness, but its diameter gradually diminished to the point, which was exceedingly sharp, and near to which was placed a hook or barb, that served to retain the weapon wherever it penetrated. Besides this arm, which was necessarily heavy, the soldiers were sometimes provided with another of the same kind, but less massive both in the wood and the iron, which they held in the left hand, and discharged immediately after the former. The *pilum* was a weapon peculiar to the Romans. As soon as they came within a proper distance of the enemy, they began the combat by launching these heavy darts, with a force which, from their weight and the temper of the steel points, caused them frequently to penetrate both buckler and cuirass, so as to inflict the most hideous and desperate wounds. Having discharged these missiles, the legionaries instantly drew their swords and rushed upon the enemy with the utmost impetuosity, before he could recover from the effects of the volley of *pila*, by which his first ranks were generally overthrown.¹ The pike of the *triarii*, a weapon equally adapted for attack or defence, onset or resistance, was longer, less thick, and consequently more manageable, than the *pilum*, which was of little use except at the moment of commencing battle. Armed with this weapon, the veteran reserve of the legion often awaited *de pied ferme*, the shock of cavalry as well as infantry; and Livy assures us that they seldom or never quitted their pikes in battle. "The *triarii*," says he, speaking of a particular occasion, "disfigured the faces of the Latins with their pikes, the points of which had been blunted in the combat." These *troupes d'élite*, therefore, may be considered as the pikemen of the legion; although instances are to be found where they abandoned the pike and had recourse to the sword, which was always the weapon in which the Romans placed the greatest confidence, and with which, indeed, their most celebrated feats in arms were achieved. It may be proper to add, that, although this description principally applies to the legion as constituted in the time of Polybius, and although great changes were subsequently introduced, yet the arms, offensive as well as defensive, of the legionaries, remained nearly the same; with this exception, however, that all the troops of the line were at length armed in precisely the same manner, namely, with the Spanish sword and the *pilum*.

The horse had very nearly the same armour as the foot, and they were latterly provided with offensive arms similar to those used by the cavalry of the Greeks; namely, with a lance, having a shaft resembling two cones joined together at their bases, and pointed at both extremities, and a long, large sword, suspended by a shoulder-belt at the right side. There was a time, indeed, when they had only slender lances, pointed at one extremity, and wore no cuirass; but experience soon showed the necessity of adopting the Greek arms and equipments. The Roman cavalry was generally composed of a superior description of men, denominated knights, who on all occasions displayed the greatest valour; but they seldom mustered in force sufficient to produce great results, and their organization appears to have been in many respects defective.

It is evident, that a man placed on the back of a horse, without a saddle, or stirrups to serve as a fulcrum for reaction, can never exert half his proper force, nor combine it effectively with the momentum acquired from the velocity and weight of his horse. "Ces cavaliers," says Rogniat, "ne pouvaient être choisis que parmi les chevaliers, qui formaient un des premiers ordres à Rome. L'état leur fournissait ordinairement des chevaux; mais, peu habitués à l'équitation, ou persuadés qu'on est plus fort à pied qu'à cheval, ils mettaient souvent pied à terre, pour prendre une part plus décisive aux combats sérieux. Telle était (he adds) l'opinion des Romains, de la supériorité de l'infanterie sur la cavalerie, que, non content de n'avoir qu'un petit nombre de cavaliers, ils les transformaient encore en fantassins dans les occasions critiques."²

The Roman generals, even in the time of the consuls, do not seem to have followed any particular order of battle, but to have changed it according to circumstances, or the nature of the enemy they had to contend with. This is evinced by the various dispositions which were made at the battles of Tunis, of Cannæ, of Zama, and many others that might be mentioned. But still the chequer order or *quincunx* was that most frequently employed in the earlier times of the republic; owing, doubtless, to the facility it afforded of forming line or column at pleasure. Leaving the *velites* or light troops out of view, as constituting no part of the main battle, the reader will observe that the maniples of the first line, or the *hastati*, were formed upon a front varying according to the depth, which was generally ten, but not unfrequently six; and that the interval between each manipule was exactly equal to its front. Thus, supposing the legion 5000 strong, a manipule of 140 men would be ranged ten deep upon a front of fourteen; and as each soldier occupied three feet,³ the extent of front presented by a manipule would accordingly be fourteen yards. Since the first line, therefore, consisted of ten manipules, it contained of course nine intervals of fourteen yards each; exactly opposite to which, but at a considerable distance in the rear, were stationed nine of the ten manipules of the second line, or *principes*, drawn up in the same manner as those of the first, upon fronts of equal extent; the tenth manipule of the latter outflanking by the whole length of its front the right or the left wing, as it might be, of the first line. The *triarii*, of less depth than the *hastati* and *principes*, but for the most part in continuous formation, occupied the third line. Now, it must be obvious at the first glance, that this order of battle presented several important advantages. By advancing the manipules of the *principes* through the above-mentioned intervals, until they dressed with those of the *hastati*, line was at once formed: again, by moving them fourteen yards either to the right or left, the depth of the formation was doubled; while, by placing the manipules of the *triarii* exactly behind those of the *principes*, as was done when the legions were menaced by elephants, the whole was formed into columns, separated into intervals equal to their respective fronts, through which these animals, pursued and goaded by the *velites*, might be driven to the rear, without doing

¹ For a particular description of the use of the *pilum* in commencing the attack, see Cæsar's *Commentaries de Bello Civili*, lib. iii. cap. 92. The weight of this arm "ne permettoit pas de le darder de loin," as Guischardt says. It was the business of the *velites* to harass the enemy with their javelins and other missiles before the action became general. As the hostile lines approached, the light troops retired through the intervals or by the flanks, where they generally took their station; and when the former were within a short distance of each other, the *hastati* and *principes* darted their *pila*, and then rushed on, sword in hand, to close combat. Hence the proverb employed by Vegetius to describe the proximity of two armies: *Ad pila et spathas ventum est*.

² *Considérations sur l'Art de la Guerre*, p. 10, 11. Paris, 1820.

³ The ranks of the manipule being also drawn up at the distance of three feet from one another, the whole space occupied by the Roman soldier was consequently nine square feet of ground; and this open order was seldom departed from, even in the charge. It is to be observed, however, that the second rank of the manipule was so disposed as to cover the intervals of the first, the third to cover those of the second, the fourth to cover those of the third, and so on to the last; in other words, the arrangement of each manipule individually was a precise type of their collective disposition in order of battle.

Army.

any mischief. Lastly, if it was desired to form the legion in three continuous lines, this was instantly effected by simply closing up the intervals between the maniples of the first and second lines; the *triarii* or reserve being, as we have already said, drawn up in a continuous formation, except when it became necessary to open a passage for elephants. And all these various evolutions were performed with a rapidity and precision which have seldom been equalled and never surpassed by the troops of any other nation.

At a later period, however, the Roman tacticians employed a different order of battle, distinguished for its greater compactness and solidity, as well as for the facility and rapidity with which it might be formed from the order of march, even in presence of the enemy. According to this method each manipule of the legion formed only a single rank in its order of battle; consequently the two classes of *hastati* and *principes*, ranged each upon its first manipule as a front, formed two lines ten deep. But as each man occupied three feet every way, and as the lines were separated by an interval equal to half the extent of their front, it is obvious that each line occupied a front of 120 yards, by from ten to twelve yards in depth; and that they were separated from each other by an interval of about 60 yards. Again, at an equal distance in rear of the *principes*, the *triarii* formed the reserve of the legion in the third line; and the whole, ranged in this manner in three lines, constituted a square order, as deep as it was broad; while the *turmæ* of the cavalry covered the flanks of the lines, and the eagle or standard of the legion was intrusted to the keeping of the *primpilus* on the right of the line of the *triarii*. This order, usually denominated *legio quadrata*, was that adopted by all skilful generals when in presence of an enemy. But the different legions composing an army were ranged upon the same principle, with reference to one another, as the different ranks of the same legion; in other words, they were formed *en echelon*; each legionary line thus making one of the sections of the column, and the baggage occupying the intervals, while the *velites* covered the flanks. In this order of march, if the enemy threatened an attack on the front, each legion in succession formed line with that at the head of the column; the second almost in an instant, the third somewhat later, and the fourth, or the most remote, in about seven minutes, which were accounted sufficient for developing the order of battle on the front. But the order of battle on the flank was of still more rapid formation. For, the baggage withdrawing from between the sections, and assembling on the side opposite to the enemy, each legion executed what is technically called a *quart de conversion* on its *hastati*, and the whole army immediately found itself in order of battle; two minutes being sufficient for the performance of this simple evolution. It seems evident, then, that the celebrated *quadratum agmen* of the Romans, which has hitherto been so often treated of, and so little understood, consisted of a certain number of *legiones quadratæ* disposed *en echelon*, or at least in column, as we have just described: and, from the advantages of this order of march, particularly its rapid convertibility into an order of battle either on the front or the flank, it is easy to understand the reason why the Roman historians have censured so severely the generals who neglected to adopt it in presence of the enemy. So much, then, for Roman tactics, as connected with the elementary formation of those brigades or divisions which constituted the units of Roman armies.

The distinguishing characteristic of the legion consisted in its astonishing mobility, united with its power of preserving its order of battle undisturbed, and of constantly rallying when forced to give way. It possessed a sort of flexibility which enabled it to adapt itself to every change and variety of circumstances; and no other military body, perhaps, ever executed so numerous evolutions in the presence of an enemy. Its attack was impetuous and formidable; but if that failed, it then displayed its most characteristic excellence, by fighting in retreat. In this way it vanquished the phalanx, although it was unable to withstand the direct shock of that dense body in the open field. At the battle where Flaminius defeated Philip in Thessaly, the Macedonian phalanx gained considerable ground on the legions; but the Romans, although forced to give way, preserved their order,—returned repeatedly to the charge,—and, even while in the act of retiring, extended their line so as to gain the flank of the Greeks. Philip durst neither accelerate his march, nor send out any detachment in pursuit; so that twenty manipules had time to turn his flank and fall upon his rear, which speedily decided the fate of the battle. As the phalanx acted with long pikes, and in close order, the least derangement caused by the ardour of the soldier in pursuit, or by inequality of ground in its march, necessarily exposed it to the legion; which, dividing itself into a number of separate corps with the same facility that it formed one corps and one line, possessed the power of attacking it on two or more sides at the same time. “La légion doit donc,” says Guischart, “être envisagée sous deux faces. Comme infanterie en bataille contre une autre infanterie, elle eut son ordonnance particulière à rangs et files ouverts, conformément à ses armes; et alors elle n'eut rien de commun avec la phalange. Lorsqu'elle a eu de la cavalerie en tête, elle cessa d'avoir son ordonnance particulière.”¹ This wise distinction rendered the legion formidable alike to every nation on which Rome chose to make war;² but neither as infantry against infantry, nor as infantry prepared to resist cavalry, which duty was principally performed by the *triarii*, until all distinction of classes and arms merged in a homogeneous formation, had it any thing in common with the phalanx; for its victories, no less than its reverses, had demonstrated the inutility of deep formations, and showed that its real power depended on its distributive rather than its concentrative energies,—on its mobility and flexibility rather than on its weight or impulsion. Hence, on the day of Pharsalia, it was remarked, as an extraordinary circumstance, that Pompey had formed his legions ten deep; a novelty which, as every schoolboy knows, served no other purpose, on that occasion, except to add to the carnage.

In following the Romans in their wars under the emperors, we find their discipline and their tactics declining from age to age, in the same manner as they had advanced and improved. The spirit of change, though productive of some ameliorations, proved ultimately fatal to the legion. As long as the Romans continued faithful to the precepts and rules of the ancient masters, their infantry maintained its superiority: in proportion as these were departed from it declined; until at length, having lost all its distinctive qualities, it was constantly beaten and overthrown by the numerous cavalry of the barbarians. To ascribe the gradual declension and ultimate fall of this infantry to luxury, refinement, love of ease, corruption of

¹ *Mémoires Militaires*, tom. i. p. 84.

² The cavalry of the Parthians, though peculiarly formidable, durst not attack the legions commanded by Marc Antony, and confined itself to harassing them from a distance with its arrows. At the battle of Nicopolis, a single legion of the army of Domitius defeated and put to flight the whole cavalry of king Pharnaces; and, with a handful of infantry and some horse, Pompey defied the numerous cavalry of king Orodes.

Any. manners, or other analogous causes, is merely to indite silly common-places, displaying the most profound ignorance of history and of human nature. Its catastrophe was occasioned by the decay of discipline alone. For experience shows that hardy and effective soldiers may be formed in the most polished as well as in the rudest and most uncivilized periods of society; and that nothing more is necessary to produce this result than an uncompromising system of discipline. Accordingly, under Vespasian, and Titus, and Trajan, and Hadrian, and Aurelian, and other warlike emperors, who enforced the precepts of the ancient masters, and restored the ancient discipline, the Roman infantry regained its reputation, and proved itself as formidable as it had ever been in the best times of the republic. The corruption was not in the soldiers, but in the men by whom they were organized; in those whom the experience of so many ages, and the conquest of the world, had failed to impress with a due conviction of the value of that system of discipline by which such prodigies had been performed. "On ne peut voir sans indignation," says Guischart, "la mauvaise ordonnance que les Romains autems de Végece avoient substituée aux anciens modèles. Ils étoient rangés sur six de hauteur, et même quelquefois sur trois. Chaque rang avoit des armes différentes, dont la plupart étoient des armes de jet, comme des arcs et des frondes. D'un rang à l'autre il y'avait six pieds d'intervalle, et dans les files on avoit retranché les trois pieds de distance, parcequ'on ne se battoit plus avec l'épée: on avoit même oublié le véritable usage du *pilum*. Le troisième et le quatrième rangs devoient de tems en tems se détacher, et charger à la tête de la ligne, et revenir ensuite à leur poste. On ne sauroit rien imaginer de plus pitoyable. Ces deux chapitres de Végece marquent bien clairement l'ignorance de l'auteur, et la décadence de la bonne discipline chez les Romains."¹ From innovations like these, and others still more absurd which succeeded them, what results could be anticipated except those which history has recorded; namely, disgraceful defeats, calamitous reverses and, at length, the final overthrow of the Roman power itself? The legions, degenerated into a feeble militia, sold the empire which they were incapable of defending; and having neither the courage which sometimes supplies the place of discipline, nor the discipline which supplies that of mere courage, they fell an easy prey to the swarms of Goths, Huns, and Vandals, by whom it was successively overrun, and at last completely destroyed.

Arms of the middle ages. The fall of the Western Empire, like that of a colossal structure, was succeeded by a thick cloud, which overspread Europe, covering it with darkness and desolation. All that remained of science or of art perished in its ruins, and the only relic of the catastrophe was the shadow of a mighty name. But the barbarians who had subverted the Roman power appear to have brought with them, from their forests and wildernesses, the elements of a system which was destined to thicken the darkness in which it originated; to bind Europe for ages in the fetters of the most abject thralldom; nay, even to maintain a long and fierce struggle against the reviving energies of the human mind, and the regenerative powers of society. Its foundations were laid in their peculiar character and habits, as affected by their position and their wants; and, as they had fought neither from the love of glory, to which they were insensible, nor from a thirst of vengeance, which nothing had contributed to stimulate, the only fruits they dreamt of reaping from victory were the spoils of the vanquished. The countries which all had con-

quered were considered the property of all, and each claimed a share proportionate to his services and the number of his retainers. Subsisting rights or possessions weighed as nothing in the estimation of these wild hordes, who sought for establishments in genial climates and fertile regions. They demanded a territorial division and apportionment, which was accordingly made upon some rude principle of equalization. But, as these lands were the reward of military service, so they were to be held by that tenure alone. The common interest and the common defence required that this condition should be annexed to the allotment, or, as it was afterwards called, the *feu*. Each great vassal of the liege lord was bound to have in constant readiness to take the field, a certain number of men, clothed, armed, and equipped at his own expense. Hence arose the *feudal system*, which, founded on military rather than civil principles, was an aggregation of petty sovereigns and petty principalities, under a nominal head, to whom all swore fealty, but few or none owned obedience; a military aristocracy, in short, under the mask of a monarchy. But this system, however well calculated to keep alive a spirit of ferocity, seemed to oppose a formidable barrier to the revival of the military art. Its maxims, necessarily hostile to the establishment of a standing army, by which the great barons might have been coerced, limited the force of the state to the contingents of feudal militia, which the crown vassals could bring into the field; a tumultuary mass, without coherence, which the first victory or the first reverse generally dispersed. During this period, accordingly, the wars of Europe were desultory and indecisive. An incursion constituted a campaign, and a foray an expedition. Armies were everywhere without order and without science; battles were gained by accident or by valour, never by discipline; while conquests, rapid as torrents, were generally as destructive and as transitory. The love of military glory was extinguished; petty wars, occasioned by baronial feuds, raged fiercely, preying upon the vitals of society; and the fruits of organized barbarism were general misery and desolation. The people were abject serfs, the barons ferocious brutes, the sovereign an absolute cipher. Anarchy, tyranny, ignorance, and spiritual thralldom, formed the characteristics of the first ages of feudalism.

At length, in the eleventh century, arose a monk, called The crusades. Peter the Hermit, who preached with all the fervour,

and more than all the success, of any known apostle, the duty of recovering the Holy Sepulchre from the infidels; and as the church lent her powerful aid to second the efforts of Peter's enthusiasm, the contagion soon spread throughout every part of Europe, and thousands of all countries rushed forward to enlist under the banner of the cross. The history of mankind affords no parallel to the madness that was thus produced, either as regards its universality or its duration. It affected all Christendom in nearly an equal degree; and, during two centuries, army after army marched for Palestine, to melt away under the sultry sun of Syria, or to be mowed down by the swords of the Saracens. But it agitated the minds of men by a new and powerful impulse; and although its essence consisted in the wildest fanaticism which had ever taken possession of the species, yet that inexplicable frenzy, combining with a spirit of enterprise and adventure, gave birth to institutions which were destined to exert a powerful influence upon the whole frame of society, and which have left a marked impression even on the manners, customs, and feelings of modern times. Viewed in a military light, the armies of the crusaders were mere

¹ *Mémoires Militaires*, prel. disc. xxiv.

Army. tumultuary masses, impelled by fanaticism to deeds of heroic valour, but as destitute of order and discipline as their leaders and chiefs were ignorant of military science; nor had all the reverses they sustained the effect of inculcating the simplest principles of the art of war, or teaching the necessity of adopting some kind of organization. Every thing was trusted to numbers without combination, and to individual bravery exerted as chance or impulse happened to direct. And so deeply engrained in men's minds was the spirit of feudalism, and so incompatible did that spirit show itself with the slightest advancement in the military art, that the mailed chivalry of the ages immediately succeeding the crusades, although offering the finest elements that ever existed for the organization of an invincible force, appears at no time to have had any principle of effective combination, or to have been capable of acting with unity and concert in any grand operation. Yet the principal strength of armies in the middle ages consisted in their cavalry; which, composed of men of superior grade, and formidable from its bravery no less than from the armour of proof in which it was encased, easily proved itself superior to infantry without formation, and with no other discipline than that which instinct dictates even to the most barbarous tribes.

Invention of gunpowder. But a new epoch approached. Gunpowder was invented, or at least improved, by Berthold Schwartz, a Franciscan monk of Cologne, and was first employed in warlike operations in the early part of the fourteenth century. This discovery, as Guibert justly remarks, did not lead to any *immediate* improvement in the art of war: indeed a century and a half was necessary in order to make the use of fire-arms general; but it is nevertheless to be considered as the real cause of the complete reform which was at last effected in the constitution of armies, as well as in their discipline and tactics. Since the first employment of gunpowder, there have been *seven principal periods* in the history of the military art.

First period. The first begins with the employment of cannon, and extends to Charles VIII.'s campaign in Italy; or from the early part of the fourteenth until towards the end of the fifteenth century. This period, during which the art of war began to revive from the state of barbarism into which it had sunk since the downfall of the Roman empire, includes the wars of the Spaniards against the Moors, of the English against the French, and finally, of the Italian republics against each other. The cavalry, composed of the nobility and gentry, still constituted the flower of armies, and formed the chief support of princes and their kingdoms. At the storming of fortresses, or when important posts were to be occupied and defended, and a bold, determined soldiery was required, the knights dismounted and fought on foot. They were the dragoons of that age. Each knight was attended by his esquire; and, besides these there were also archers, generally the vassals of the knights, who, being more lightly armed, and riding smaller horses, served as a kind of light horsemen. At the beginning of the fourteenth century, indeed, the distinction of heavy and light horse was common in European armies. The former, consisting of tenants *in capite*, holding of the crown by tenure of military service, or their substitutes (*servientes*), were denominated *men-at-arms*, from their being armed *cap-à-pied*; the latter, composed of yeomen, were named *hobilers*. The knights rode what were denominated war-horses, which, like their riders, were

covered either with chain or plate armour, or with both; and these men of iron carried a long and powerful lance armed with an iron head, a long sword, a short sword, a dagger, and a mace or battle-axe.¹ Their formation for combat was exceedingly simple. They fought man to man; each armed knight singling out his opponent, and riding against him with his couched lance, in order to throw him out of his saddle, or to make him prisoner. The esquires, or armour-bearers, followed as a second rank, or at least acted as seconds to the knights, whom they assisted in battle, bringing them fresh arms and horses when required, and seeking opportunities of distinguishing themselves in order to obtain the honour of knighthood. Nothing, however, was known of scientific movements, until Charles the Bold compiled an exercise book in 1473, instructing cavalry how to attack in close and extended order, or to link the horses and fight on foot. An engagement was generally commenced by single knights riding forward and challenging opponents from the hostile army; and the result of these single combats sometimes determined the fate of the day.²

The second period, from the campaign of Charles VIII. in Italy to the beginning of the wars in the Netherlands, or from the end of the fifteenth to the middle of the sixteenth centuries, comprises the wars of the French, Spaniards, and Germans, in Italy. During this period chivalry gradually declined, and war began to assume a new aspect. At the close of the contest with England in 1445, Charles VII. of France established the first standing army, consisting of 16,000 infantry and 9000 cavalry, divided into fifteen *campagnes d'ordonnance*;³ he appropriated funds for the payment of these troops, and appointed officers to discipline and command them; and, although apprehensive at first as to the success of the experiment, he at length succeeded in organizing a force, which enabled his successor to repress the turbulent spirit of the feudal aristocracy, to strengthen the power of the crown, and to carry on foreign operations with a consistency and vigour hitherto unknown. The Italian campaign of Charles VIII. proved the superiority of a standing army over an assemblage of feudal militia, and consequently established its reputation. With a force of about 20,000 men, he overran the whole of Italy; and, had his ambition been equal to his success, or rather had he known how to reap the fruits of victory, he might have rendered himself permanent master of that country. Other nations imitated the example of France: a change took place in the military system of Europe: the practice of calling out knights ceased of itself: and mercenary, or at least paid troops, regularly disciplined and organized, became the only force that was trusted or employed. The characteristic of this period was deep formation, both in the cavalry and the infantry.

The third period comprehends the great war of independence, carried on by the Netherlanders, in order to emancipate themselves from the yoke of Spain; and it extends from 1568 to the general suspension of hostilities in 1609. Here fought, on one side, art, and an army formed by the experience of more than half a century of war, under Charles V. and his son Philip II.; on the other, the inhabitants of the Low Countries, living only by trade and the arts of peace. A people, consisting chiefly of manufacturers and merchants, inhabiting a country of small extent, and already much exhausted by a long-continued exercise of tyranny and oppression, scrupled not

¹ Meyrick's *Critical Inquiry into Ancient Armour*, vol. i. p. 174. Chain-armour first became covered with plates at the beginning of the fourteenth century; but entire plate-armour did not make its appearance until about a century after.

² The only military productions of this period were the regulations of Charles the Bold, above-mentioned, with those of Louis VII. of France, and of John Ziska, general of the Hussites.

³ See Père Daniel, vol. i. p. 155.

Any. to draw the sword, in defence of their liberties, against the richest monarch of the age, the sovereign of Spain and the Indies, and master of the most numerous as well as the best-disciplined forces, commanded by generals distinguished above their contemporaries by their skill in the art of war.¹ A more unequal contest cannot well be imagined; and never was the issue of any dispute more contrary to what the parties had reason to anticipate. But the struggle was protracted; and in proportion as the Netherlanders were formed to war, the bravery and discipline of the Spaniards relaxed. Under the skilful tuition and able conduct of Nassau, the foe which had at first appeared so contemptible to the haughty Spaniards, tore the laurels from their brows, and at length drove them, defeated and disgraced, from the country which had suffered so long under their grinding oppression and their insolent misrule. This war was followed by great changes, both in the organization and tactics of armies. The cavalry was divided into cuirassiers and light horse; the use of the lance was discontinued,² and its place supplied by the sword and pistol for the heavy, and the carbine for the light horse; and these were now trained to execute a variety of movements and manœuvres at full speed. The infantry was also placed upon a better footing, both in respect to discipline and formation; although the prejudice in favour of columns or masses seems still to have continued, notwithstanding frequent experience of their inutility, as well as of the destruction to which they were exposed from the concentric fire of artillery.

Four. The fourth period comprises the Thirty Years War, the pretext for which, according to Bulow, was the happiness of heaven, but the motive the goods of the earth: it extends from 1618 to 1648. The peace which had terminated the struggle for independence in the Low Countries, after a protracted contest of above half a century in duration, lasted only nine years; when a new war broke out, which can only be considered a continuation of the former. The hero of this war was Gustavus Adolphus; and he, like Prince Maurice of Nassau,³ was the creator of new tactics. This warlike monarch departed from the dense formation of his predecessors, and drew up his infantry six deep; which was considered an innovation that nothing but his success could justify. His opponents, Tilly and Wallenstein, formed their infantry in solid masses thirty deep; which, nevertheless, proved unable to contend with the linear formation of the Swedish troops. Until about the middle of this war, it still continued the practice to form cavalry in from four to eight ranks. But Gustavus also departed from this rule, and formed it in three ranks; although it appears from Harte, that, at the battle of Leipsic, it was drawn up four deep, probably on account of the dense formation of the imperial cavalry, which was formed in eight ranks. In the intervals he stationed platoons of infantry, fifty and upwards strong, as well as light guns; doubtless from a conviction that cavalry, unless supported, were unable to contend with infantry. His great object appears to have been, to give greater mobility to the

two principal arms of a military force, and thus to gain in celerity of movement what he had lost in weight or impulsion. He knew that the momentum would remain the same, if the motion was increased proportionally to the diminution in weight.

Army. The fifth period comprehends the wars of the French Fifth in Italy, in Germany, and in the Netherlands, as well as period. the northern and Turkish wars, and embraces a period of ninety years; namely, from 1648 to 1738. The peace of Westphalia put a period to nearly a century of war. The results of this conflict were the secularization of ecclesiastical property, the complete establishment of the Protestant religion, the recognition of mental freedom, the decay of the Papal power throughout Europe, and the triumph of national independence. But during the long-continued struggle in Germany, two hereditary enemies appeared,—the Turks and the French. The former were expelled in a single campaign, and never again attempted any serious invasion. The latter entered upon a series of wars of which we have not yet probably seen the termination. The ambition of Louis XIV., however, and the wars to which it gave rise, rapidly developed the art of carrying on military operations, and formed generals whose names adorn military history. Opposed to a French Turenne, Luxembourg, and Condé, stand Montecuculi, Marlborough, and Eugene of Savoy: Louis of Baden may rank with Catinat or Vendôme; and many other generals of eminence illustrate this period, which was less remarkable for changes in the constitution and organization of armies than for the talents displayed in conducting their operations in the field. It was the era of great commanders. In the north the Swedes, Poles, Brandenburgians, and Muscovites, fought alternately on the plains of Poland and the steppes of the Ukraine. Under Charles XII. the Swedish infantry attained a high degree of perfection, and proved uniformly successful until it was so rashly committed at Pultowa; while the cavalry, without defensive armour, which the chivalrous monarch rejected, consisted almost entirely of dragoons.⁴ The principal improvements of this period, however, are chiefly due to the French, who made rapid advances in all the branches of military science.

The sixth period includes the three Silesian wars; Sixth namely, from the beginning of the first Silesian war in period. 1740, to the breaking out of the French revolutionary war in 1792. For a century previous to this, Prussia appears to have been chiefly employed in preparing herself for the brilliant part which she acted under Frederick II. To the celebrated elector, Frederick William, the Prussian military power in a great measure owed its origin. This prince grew up, as it were, in a camp, and even in his boyish days, was present at the sieges of Breda and the Schenkenschantze. Arrived at the government, he endeavoured to infuse a new spirit into the army; and so well did he succeed, that, in 1672, he was enabled to promise the republic of Holland an auxiliary force of 20,000 men. At the period of his death the elector left behind him a well-organized army of 30,000. When Frederick the Great (or, as he

¹ Watson's *History of Philip II.* vol. i. p. 428.

² "La lance," says Montecuculi, "est la reine des armes pour la cavalerie." (*Mémoires*, liv. i. c. 2.) And this opinion seems to be gaining ground at the present day; for experience has shown, that cavalry can never make any serious impression by means of fire-arms, while, with swords alone, they are wholly unfit to contend with infantry.

³ Bismark's *Cavalry Tactics*, p. 307; Guibert, *Essai Général de Tactique*, p. 68.

⁴ Charles XII., not content with making the cavalry, without any connection with or dependence upon other arms, but from confidence in itself, charge the enemy's horse at full speed, without firing, led it equally against intrenchments and batteries, and always with success. "He knew," says Count Bismark, "that by the rapidity of motion, the natural vivacity of the majority of mankind is increased, and, often mounting to a blind fury and foolhardy enthusiasm, leaves no time for consideration or calculation of danger; that at such a moment death loses its terrors, and Victory!—but with living colours—presents itself to the soul of the wildly-rushing warrior." (*Cavalry Tactics*, p. 319, 320, 321.) At the same time Charles appears to have had a love of fighting for its own sake; and it was probably this peculiarity of temperament, as much as any calculation of results, which gave to his movements that impetuosity, which neither natural nor artificial obstacles could check or resist.

Army.

is called by the Germans, *der Einzige*, the Unequalled) ascended the throne, he found the army about 80,000 strong, and drilled to a precision of movement, as well as a rapidity in firing, until then unknown. This was owing to the exertions of Prince Leopold of Dessau, who may be considered the founder of the modern system of tactics, having invented the iron ramrod and the equal step,—reduced the formation of the infantry from four to three ranks, thereby increasing the effect of musket fire,—and, in short, laid the foundation of the system which Frederick afterwards improved, by giving to infantry-movements greater lightness and facility. With an army thus prepared for action, Frederick took the field in 1740. But the first two wars passed quickly by; and the intervals of peace were employed in reforming whatever experience had shown to be defective in his system,—in practising a vast variety of deployments,—and, above all, in introducing that celerity of movement which had become so essential in modern armies, with reference both to their numbers and the extent of their front. When the third Silesian or Seven Years War broke out, Frederick, forsaken by his allies, and menaced on all sides by powerful enemies, seemed on the very verge of destruction. But if he stood alone, he stood unmoved, like the oak, braving the storm, and conscious of the power to weather it. Nor was he without some peculiar and decided advantages. On the one hand, his natural *coup d'œil*, which was perfect; the unity and power of his will; the habit of his troops to remain firm in all situations, and to execute every movement with precision, even in the very tumult of battle; the never-shaken confidence in their leader, and the enthusiasm with which he was regarded by them: and, on the other, the division, weakness, and want of system or connection in the enemy's plans of operation; their partial and lukewarm mode of execution; together with the inferiority of their troops in organization, and of their commanders in genius:—these were the causes which enabled Frederick to retire from this bloody seven years conflict with a prodigious increase of fame, and without the loss of an acre of territory.¹ “Depuis la guerre de la Succession,” says Guibert, “on n'avoit pas vu tant d'armées en campagne et réunies contre un seul prince. Sa science et leurs fautes furent le contrepoids de tant de forces. Jamais guerre ne fut plus instructive, et plus féconde en événemens. Il s'y fit des actions dignes des plus grands capitaines, et des fautes dont les Marsin auroient rougi. On y vit quelquefois le génie aux prises avec le génie, mais plus souvent avec l'ignorance. Partout où le roi de Prusse put manœuvrer il eut des succès. Presque partout où il fut réduit à se battre, il fut battu: événemens qui prouvent combien ses troupes étoient supérieures en tactique, si elles ne l'étoient pas en valeur.”² Such was the character of the Prussian army of this period, and such the military genius of the great monarch by whom it was commanded. Mere tactical details are foreign to the object of this article, and therefore we abstain from entering into them, excepting in as far as they may seem necessary to throw light upon the constitution and composition of armies. That of Prussia was long considered a model for imitation. Under Generals Siedlitz and Ziethen its cavalry attained a degree of perfection unequalled either before or since. “There was but one Seidlitz,” says Count

von Bismark. In playing the mighty game of war, its infantry was also superior to any other of that age; and if subsequent events somewhat tarnished its reputation, it has never ceased to be one of the best organized and most completely equipped bodies of foot in Europe. The Austrians, as their wont is, only improved on compulsion, and when fairly beaten out of their old system of masses and deep formations.

The armies and the science of this period, however, were destined to be far outnumbered and surpassed in period. The seventh and last, which embraces the military systems and establishments of our own times. These, accordingly, we shall now proceed to describe in detail; confining our accounts principally, if not exclusively, to their actual rather than to their former condition and strength; and commencing with the army of France, which has not only played a most conspicuous part since the commencement of the revolutionary wars, but has latterly served as a sort of model on which the other armies of Europe have been more or less formed.

From time immemorial, the Gauls were inhabited by a French race of men distinguished for their bravery. Hardy and enterprising under the two Brenni, obstinate and persevering in their attacks against Cæsar, we find them cutting a conspicuous figure as auxiliaries in all the wars of ancient Rome. They passed through the middle ages with equal distinction; and if they were forced to yield to the irruption of the Franks, the amalgamation of the two nations had only the effect of adding to their energy. The wars of Charlemagne and the crusades; the successive invasions of Italy by Louis XII., Charles VIII., and Francis I.; and, lastly, the struggles maintained against all Europe by Louis XIV., showed what might be expected from French armies when properly commanded. But the fatal results of the Seven Years War, the wretched intrigues of the court of Louis XV., and still more the spirit of infatuation which appears to have become endemic after the disgraceful Hanoverian expeditions, eclipsed, in an instant, ages of glory, and rendered the army of France an object of ridicule to Europe. After the peace of 1762, some measures were taken with the view, as was pretended, of remedying the supposed defects in the constitution of the army, and restoring its character. But the French ministry of that day, ignorant of the real circumstances which had led to its successive defeats, and incapable of comprehending the dispositions and strategical movements by which success in war is attained, contented themselves with searching into the most minute details of discipline and instruction for the causes of failures which were solely attributable to a bad choice of generals, and a faulty direction of great operations. They imagined that the armies of Frederick had triumphed in consequence of oblique marches, the particular cut of their uniforms, and a thousand other absurdities which it would be impossible to credit, were not the amusing discussions of that period embodied in public documents of unquestionable authenticity; they disputed about ployments and deployments *en trois*, about *tranches* and *plesions*, about a Prussian order and a French order; they formed camps in order to judge of the advantages of these different systems; and they fancied that they had discovered the sublime of the art in the mechanism of the instruction of platoons.³

¹ Bismark's *Cavalry Tactics*, p. 323.

² “On étoit si fort engoué de tout ce qui ressembloit à la tactique Allemande,” says Jomini, “qu'il suffit à cette époque de porter un nom Tudesque pour faire une fortune militaire. Un certain capitaine Pirch, sorti des rangs de l'armée Prussienne, passa pour un émule de Frédéric, sur la simple présentation d'un mémoire dans lequel il donnait des idées pour aligner des bataillons sur les drapeaux; on se crut heureux qu'il daignât accepter un régiment et l'instruire suivant sa méthode.” (*Histoire Critique et Militaire des Guerres de la Révolution*, tom. i. p. 214.) Under the government which promoted Pirch, and indeed under that which succeeded it, Kléber, Moreau, and even Napoleon himself, would have been condemned to an eternal nullity.

³ Guibert, *Essai Général de Tactique*, tome i. p. 77, 78.

Army.

Army.

Army.

"Encore un pas retrograde," says Jomini, "et les troupes Françaises se fussent trouvées au niveau des soldats du pape."¹ But the American war gave a check to these mischievous fooleries, and revived the spirit of emulation, which is the source of the most brilliant feats in war; while the expeditions to Grenada and St Eustatius, together with the campaigns of Lafayette, Saint-Simon, and Rochambeau, in a great measure restored the reputation of the French arms, and prepared the way for still more important achievements. The staff, the government, and the *faiseurs* were still divided between different systems. But while the chiefs were perplexing themselves with theories, the troops improved both in discipline and manœuvres; and had it not been for the repeated shocks which their organization experienced in consequence of frequent changes of ministry, and the introduction of certain radical innovations, which completely broke up the old battalions in order to amalgamate them with new levies, Louis XVI. would have possessed an army capable of defending the monarchy, and might have been able to restrain and resist that revolutionary frenzy to which he was destined soon to become a victim. In consequence of the disorganization thus introduced, the regiments of the line were in a wretched condition at the breaking out of the war in 1792. But a single measure saved them from destruction. The nomination officers taken from the *tiers-état* filled the ranks with an ambitious and warlike youth, burning to distinguish itself; while emulation, the chances of preferment, and the love of country, supplied for a time the want of discipline, and formed powerful motives for stimulating improvement.

At the end of the year 1791, the French infantry consisted of 105 regiments of two battalions each, 14 battalions of light troops, and 170 battalions of national volunteers; or 394 battalions in all. By the decree of the 5th May 1792, the number of the volunteer battalions was raised to 200, and the strength of each was increased from 226 to 800 men. The cavalry was composed of two regiments of carabineers, consisting of four squadrons each; 24 regiments of heavy cavalry of three squadrons each; 18 regiments of dragoons of three squadrons each; 12 regiments of chasseurs of four squadrons each; and 6 regiments of hussars of three squadrons each; in all 206 squadrons. So that the total strength of the French army at this period did not exceed 160,000 infantry, 35,000 cavalry, and 10,000 artillery; while 20,000 men were still wanting to bring the different regiments to their full complements. But this deficit was soon supplied by the multitude of volunteers who flocked to the national standards when the duke of Brunswick invaded France at the head of the Prussian army.² The revolution, however, had not yet developed its energies; nor had the world as yet any suspicion of the prodigies which the system of terror, afterwards organized, was destined to achieve. In 1795, France presented the formidable aspect of a vast camp. The decrees of the 23d August and the 5th September 1794 had hurried the whole youth to the frontiers. Nearly 1,200,000 men were in the pay of the republic; and, after deducting those employed in accessory services, and in the navy, the number of combatants in the field cannot have amounted to less than about 700,000. The official state of the force of the French armies, as at the 5th April 1794, presents an aggregate of 794,334 men, including garrisons, but exclusive of the army of the interior, whose head-quarters were at Paris; which, allowing one fifth for those in the depôts and for the sick, would give an effective force, present under arms, of at least 650,000 men; the most formidable which Europe

had ever seen assembled in the field. "Ce développement de forces, sans exemple dans les annales modernes," says Jomini, "tenait d'autant plus du prodige, que la nation se trouvait livrée à tous les déchirements d'une guerre civile, et aux persécutions d'un gouvernement odieux. Mais ce ne fut pas aux levées seulement que ces efforts se bornèrent: tout ce qui compose les élémens de la puissance nationale, avoit été porté à un degré de tension inconnu dans les siècles modernes."³ Nor did the "prodigy" stop here. In the month of March 1795, France had ten armies in the field, the active force of which amounted to 449,930 combatants, besides 120,850 in garrisons, and 388,450 sick, prisoners, or detached; in all 959,190 soldiers. But the active force, or number present under arms, did not form the half of the effective, and scarcely a third of the complete military strength of France at that period; for, as 200,000 men were still wanting to bring the effective force up to the full establishment, and as the most active measures were in progress to make up the deficit, the total number of Frenchmen under arms in 1795 cannot have fallen much short of 1,100,000 men. It will not be denied, therefore, that the *Comité du Salut Public* possessed extraordinary energy, and that terrorism proved the salvation of France.

But this state of exertion was too violent to be of long continuance; and neither the population of the country, nor its exhausted resources, were sufficient to maintain so enormous a force in the field. Accordingly, in the succeeding years of the republic, the aggregate of the different armies seldom exceeded 480,000 effective men, and generally fell short of this number. But when Napoleon had mounted the throne, and had organized the system of conscription, he obtained an unlimited command over the whole of that part of the population capable of bearing arms; and as he acted upon the principle, first recommended by Cato, of making war support itself, he was not only able to repair the losses sustained in his various campaigns, but, on most occasions, to take the field with a predominating superiority of numbers. The establishment of the French army, in 1805, amounted to 341,412 infantry of the line, 100,130 light infantry, 77,488 cavalry, 46,489 artillery, and 5445 engineers; making a total of 650,964 men; or a force equal to that organized by the terrorists in 1794 and 1795. But this establishment was afterwards greatly increased; and it is calculated that, at the time of the Russian campaign, there were in the depôts, in the hospitals, and in the field, not less than 1,200,000 men, of whom about 850,000 might be considered as effective. Hence, we are enabled to account for the extraordinary phenomenon of Napoleon's appearance in Germany at the head of a new and formidable army, within a few months after the annihilation of his veteran masses amidst the steppes, snows, and frosts of Russia, and making head for more than a year afterwards against the utmost efforts of the allied powers.

One of the first cares of the Bourbons, on their second restoration in 1815, was to re-model the army, and place it on a footing adapted to the new order of things. The most obvious maxims of policy recommended a proceeding which alone could give stability to the restored dynasty. But such changes are necessarily the work of time; and we need not therefore wonder that nearly ten years should have elapsed before this important object was accomplished. The French army was re-organized, augmented, and placed on nearly the same footing on which it now stands, in virtue of three royal ordinances, dated the 27th February 1825; the first of which relates

¹ *Guerres de la Révolution, ubi supra.*² *Ibid.* tom. i. p. 224-25.³ *Ibid.* tom. v. p. 20.

Army. to the infantry, the second to the cavalry, and the third to the artillery and engineers.¹ The actual military establishment of France has been deduced partly from these documents, and partly from others of a more recent date, containing particulars of the modifications and changes subsequently introduced.

The *infantry* is composed of 6 regiments of the guards and 64 of the line, 20 regiments of light infantry, and 7 foreign regiments; in all 97 regiments. Each regiment consists of a staff and three battalions, and each battalion of eight companies, viz. one of grenadiers or carabineers, another of voltigeurs, and six of fusileers or chasseurs. The peace establishment of a battalion was fixed by the ordinance of the 27th February 1825 at 600, and the war establishment at 900 men; nor has any very material change since taken place. The staff of all the regiments of the guard and of the line consists, in time of war as well as peace, of a colonel, a lieutenant-colonel, three *chefs-de-bataillon*, a major, three adjutant-majors, a paymaster, a superintendent of clothing, a standard-bearer, a chaplain, a surgeon-major and two assistants; in all 16 officers. The officers of companies, 72 in number, consist of 6 captains of the first class, 18 of the second, 12 lieutenants of the first class, 12 of the second, and 24 sub-lieutenants or ensigns. The total of non-commissioned officers in a regiment of the guards amounts to 380, in one of the line to 259; while the entire strength of both, including officers, non-commissioned officers, and soldiers, is very nearly the same.

The *cavalry* is composed of 2 regiments of grenadiers, 2 of cuirassiers, 1 of dragoons, 1 of chasseurs, 1 of lancers, and 1 of hussars, forming the two divisions of the royal guard; and of 2 regiments of carabineers, 10 of cuirassiers, 12 of dragoons, 18 of chasseurs, and 6 of hussars of the line. Each of the regiments of cavalry of the guard and of the line is composed of a staff and six squadrons. The staff consists of the colonel, a lieutenant-colonel, *chefs d'escadron*, major, instructor-in-chief, adjutant-majors, paymaster, superintendent of clothing, standard-bearer, chaplain, surgeons, captains, lieutenants, and sub-lieutenants, 65 in all. The non-commissioned officers amount to 167 for war, and 163 for peace; and the entire strength of a regiment of the guards is 940 and 748, of a regiment of the heavy cavalry 926 and 734, of a regiment of light cavalry 1022 and 734, for war and peace respectively.

The *royal corps of artillery* is composed of an appropriate staff, of artillery troops attached to the royal guard, and of artillery troops of the line. The staff consists of 390 officers, including the general officers, inspectors of this arm, who also form part of the general staff of the army,—and of 560 *employés*. The officers composing the staff are, 1 lieutenant-general, inspector-general of the central service; 9 lieutenants-general; 16 major-generals; 36 colonels, directors of artillery, inspectors of establishments, commanding *en second* the military schools, and attached to the general direction of the powder manufactories and to the central dépôt; 86 lieutenant-colonels, sub-directors, heads of establishments, and adjuncts to the commandants of schools and the central dépôt; 72 *chefs-de-bataillon*, sub-directors, heads of establishments, adjuncts to the central dépôt and to the ministry, commanding the artillery in fortified places, and aides-de-camp; 110 captains, heads of establishments or acting under them, adjuncts to the central dépôt and to the ministry, commanding the artillery in places of strength, and aides-

de-camps; 60 in fixed residence; and 50 sub-lieutenants, pupils. The *employés* consist of 1 examiner of artillery; 10 professors of mathematics, and 10 tutors in the same branch; 11 professors of design; 15 master artificers; 290 artillery guards, viz. 16 of the first class, 64 of the second, and 210 of the third; 103 workmen; 31 controllers of the manufacture of arms, and 38 of management; 36 accountants; 3 controllers of the founderies, with 3 assistants; and 3 controllers of the forges, with 3 assistants. The troops of the artillery of the guard form a brigade under the orders of a major-general of the corps, who is permanent inspector; and this brigade is composed of one regiment of foot, one of horse-artillery, and one of the train. A regiment of foot-artillery is composed of a staff, of eight companies of cannoneers, and of a detachment of workmen; amounting in all to 916 and 668 for war and peace respectively. A regiment of the horse-artillery is composed of a staff and 4 companies of cannoneers, or 454 and 382 respectively as above. A regiment of the train of artillery is composed of a staff, with 12 companies in time of war and 6 in time of peace, or 1474 and 524 respectively. Eight *employés* are specially attached to the artillery of the guard for the service of the school and the direction of the matériel, viz. a professor and a teacher of mathematics, a master artificer, three guards, and one principal workman. The artillery of the line is composed of 8 regiments of foot, 4 regiments of horse-artillery, 1 battalion of a pontoon-train, 12 companies of workmen, 1 of armourers, and 8 of the train. Each of the 8 regiments of foot-artillery consists of a staff and 20 companies; each of the regiments of horse-artillery of a staff and 8 companies. The pontoon-train is divided in 12 companies; and each of the 8 squadrons of the train is composed of a staff with 16 companies in time of war, and 8 in time of peace.

The *corps of engineers* consists of three regiments, each composed of a staff and three battalions, with a skeleton company as a dépôt, while each battalion is formed of 8 companies, 2 of which are miners and 6 sappers. The regimental staff of each regiment of engineers consists of 1 colonel, 1 lieutenant-colonel, 4 *chefs-de-bataillon*, one of which is commandant of the regimental school, 3 adjutant-majors, 1 paymaster, 1 superintendent of clothing, 1 standard-bearer, 1 chaplain, 1 surgeon-major, 2 assistants, and 3 professors attached to the regimental school; in all 16 officers. The sub-officers and workmen are 23 in number; the strength of a company of sappers or miners is 102 in peace and 150 in war; while that of a regiment, including the *cadre de la compagnie de dépôt*, is 2604 and 3756 respectively.

It follows, then, taking the totals of the different corps d'armée conformably to this analysis, that the peace establishment of the French army is fixed at 280,270 infantry and 57,057 cavalry; and the war establishment at 395,500 infantry and 105,347 cavalry. In point of fact, however, the effective force of 1826 consisted of no more than 227,667 infantry and 47,834 cavalry.² Nor have these respective numbers been since materially increased; for the effective force of 1829, as estimated in the budget of that year,³ amounted only to 232,367 infantry and 47,258 cavalry; while, in the budget for 1830, the infantry is estimated at 231,597, and the cavalry at 46,416. But some important changes have taken place since the revolution of July 1830.⁴ The Swiss guard has been discharged; the *garde royale* has been dissolved; and the whole of the

Army. *garde du corps* has been broken up. The effective force of each regiment of infantry of the line has also been fixed at 1500, of each regiment of cavalry at 700, and of each regiment of artillery and engineers at 1200 men. This may at first sight appear a considerable reduction; but if we take into account the numerous battalions of national guards which have been organized since the expulsion of the elder branch of the Bourbons, we shall find that the reduction is more apparent than real.

The French army is at present recruited partly by voluntary enrolment for a term of years, and partly by requisitions; in other words, on nearly the same principle which obtained before the revolution of 1790. The system of requisition is of course subsidiary or supplementary to that of voluntary enlistment; but, in the event of another war, it would unquestionably become the principal, if not the only, resource of the army. And this applies to other nations as well as to France. Modern manners, customs, habits, and pursuits, are primarily adverse to the military service; and this opposition can only be overcome by a conscription of one kind or other. Napoleon laid it down as a principle, "que la conscription est le mode de recrutement le plus juste, le plus doux, le plus avantageux au peuple."¹ But without being prepared to go this length, it may be admitted that it is equal in its operation; that its results are certain; and that the supplies it furnishes are of the best quality: whilst voluntary enlistment is at best a precarious resource, and sends to the ranks little else than the scum and dregs of the people. At the same time, the French army, as at present constituted, bears a much smaller proportion to the entire population of the country, and is consequently less burdensome, than that of any other nation of Europe, England only excepted. Russia, for example, requires one man in 97 for her peace establishment, and one in 57 for war: Austria takes one in 60 during peace, and one in 40 during war: Prussia, maintaining a war establishment in peace, withdraws one man in 22 for the service of her army: whilst France requires only one in 137 for peace, and one in 80 for war.² The peace establishment of Great Britain presses even more lightly upon the general mass of the population; but, in the event of a war, the proportion would, all in probability, become as unfavourable for the people as that of the French conscription under Napoleon, namely, one in 33 or 34. Such, at least, was the case during the greater part of the last war, particularly after the rupture of the short-lived peace of Amiens.

The national character of every people is commonly developed in a very striking manner by its army. "The Frenchman," says Count Bismark, "courageous, impetuous, nay, even terrible in attack, does not possess that cold-blooded, quiet circumspection and endurance which is so indispensable in a defensive war;" and hence he concludes that a war against the French ought to be carried on *offensively*. "A cautious but not the less uninterrupted offen-

sive, must be the ruling principle in all projects of operation against the French."³ Major Beamish delivers a similar opinion. "The French," says this officer, "have, with much judgment, generally endeavoured to become the *attacking* party. They thus not only derived the usual advantage of that system, but adopted the mode of warfare which was peculiarly suited to their national character. The French soldiers are impetuous; but their courage requires excitement, to which *motion* so much contributes. Abstract motion, however, is not sufficient to impel the French soldier into action: he must be first excited by the example of his officer; and were it not for the extreme and universal gallantry displayed by the officers of the French army, few instances of impetuous courage would be recorded on the part of the men. It has been said that 'the French officers will always lead, if the men will follow;' and there have been instances where the former have nobly sacrificed their lives to produce this effect"⁴ General Foy, whose endeavours to depreciate the British are at such variance with the better points of his character, says that "to Frenchmen you must always speak," and that "the intoxication of the French is gay, sparkling, and daring; a foretaste to them of the battle and the victory."⁵ A still higher authority confirms these opinions. "Le Français, naturellement brave, actif, et impétueux," says Baron Jomini, "fait aisément des conquêtes, mais il les perd avec la même facilité. Dès qu'il cesse de marcher en avant, une sorte de dégoût s'empare de lui; il est difficile de le contenir. Depuis la révolution, surtout, cette disposition s'était accrue de plus en plus: les liens de la discipline ne retenant plus le soldat, il était devenu mutin, raisonneur, et indocile."⁶ Colonel Napier's opinion appears substantially to coincide with that of Jomini and other competent judges.⁷ In fact, no military nation of Europe has gained so many splendid victories, and sustained so many disgraceful defeats, as the French; whose whole history, indeed, consists of an extraordinary alternation of the most brilliant successes and the most calamitous reverses, of triumphant ascendancy and abject humiliation. "Aucune nation," says Guibert, "n'a perdu de batailles aussi honteuses, aussi décisives, que la nôtre; aucune n'en a gagné si peu de décisives et de complètes."⁸

The Spanish army, which, under Charles V., Pescara, Spanish the Duke of Alba, and the Constable of Bourbon, had ^{Spanish army.} proved itself so formidable—extending the theatre of its exploits from the Pyrenees to the Po and the Adige on the one hand, and to the Elbe, the Meuse, and the Waal on the other—degenerated rapidly under the disastrous reigns of the last princes of the House of Austria. When Philip V. ascended the throne at the beginning of the last century, it scarcely amounted to 15,000 men. By that prince and his successors, however, it was gradually increased, until, in the year 1792, its establishment amounted to 116,000 infantry, 12,200 cavalry, with upwards of 10,000 artillery, and its effective force to about 120,000 men of

¹ Napoleon having established "qu'un million d'âmes fournit chaque année 7000 à 8000 conscrits, et que les besoins de l'administration et des divers états n'en réclamaient que moitié," he therefore concluded, "qu'une levée annuelle de 3500 hommes n'offrait, deduction faite des morts, que 30,000 hommes en dix ans," or about a 33d part of the entire population. (See Rogniat, *Réponse aux Notes Critiques de Napoleon*. Paris 1823.) But the draughts on the population of France were never carried to the full extent of the principle, and seldom exceeded one in 43 or 44.

See also vol. iii. p. 329, where, in describing the attack of the British position on the crest of the Sierra de Busaco, 27th September 1810, Colonel Napier renders justice to the "astonishing efforts of valour" on the part of the French, and ably discriminates the respective characteristics of the troops engaged on that occasion. The onset of the French was truly terrible, and at one moment had very nearly succeeded.

⁸ *Essai Général de Tactique*, tom. i. p. 176.

Army.

all arms. At present its effective amounts to 90,000, and its disposable force to 75,000 combatants. It is composed of the general active staff, of the staff of the fortresses, of the household troops and royal guard, of the infantry and cavalry of the line, with artillery, engineers, and veterans. Its staff consists of 6 captain-generals, 77 lieutenant-generals, 122 major-generals, 350 brigadier-generals, with inferior officers in proportion. There are 15 captaincies, viz. 12 territorial and 3 colonial. In Spain, and its possessions contiguous to the Peninsula, there are 150 fortresses, posts, forts, citadels, or open towns where troops are in garrison. The household troops consist of six squadrons of the body guard and a company of halberdiers: of these four squadrons are Spanish, and two foreign, called Saxons, in honour of the queen. The royal guard is organized like that of France, and consists of two divisions of infantry, one division of cavalry, and three companies of artillery, one of which is horse-artillery. The first division consists of four regiments of grenadiers, each composed of two battalions, divided into eight companies of 120 men each; and the second of two regiments of the élite of the provincial militia, divided into three battalions of four companies each. The cavalry forms a division of two brigades; and the artillery consists of three companies of 100 men, each serving a battery of six pieces mounted. The infantry of the line consists, first, of 10 regiments of three battalions each; secondly, of the Swiss regiment Wimpffen, one battalion only; thirdly, of a regiment, fixed at Ceuta, composed of four companies of 100 men each, the refuse of the army. Seven regiments, of two battalions each, of the same number and composition as those of the line, form the light infantry. The militia consists of 42 regiments of one battalion each, which is divided into eight companies. The cavalry consists of 13 regiments, of which 5 are of the line, and 8 light horse, each of four squadrons, composed like those of the royal guard; together with two companies of cuirassiers at Ceuta, one formed of native Spaniards, and the other of Moors. The royal corps of artillery is divided into the theoretical and practical. The troops of this arm consist, first, of 6 battalions of foot artillery, in garrison at Barcelona, Carthage, Seville, Corunna, and Valladolid; secondly, of 4 companies of horse-artillery, in garrison at Carthage and Seville; thirdly, of 5 companies of artificers; fourthly, of 5 battalions of the train; fifthly, of 3 brigades and 15 companies fixed in garrison, but exclusive of the *personnel* in America. This arm has a splendid museum at Madrid, besides a theoretical and practical school, directed by a brigadier-general or colonel; in the principal town or place of each province. The engineers are a corps of officers not regimented or brigaded, consisting of an engineer-general, 10 directors sub-inspectors, 17 colonels, 20 lieutenant-colonels, 34 captains, and 56 lieutenants; together with a regiment of sappers, consisting of 2 battalions of 8 companies each, viz. 5 of sappers, 1 of miners, 1 of pontoneers, and 1 of workmen. The establishments of this arm are, a topographical dépôt-general, or collection of maps, plans, and military memoirs; a museum, containing representations in relief of the fortresses, and different models of fortifications; and an academy for the instruction of young officers intending to enter this branch of the service, after they have passed through the primary school of Segovia. All these establishments are situated in the capital.

Arm

The Spanish army is recruited by voluntary enrolment, and, in case of insufficiency, by ballot or conscription. The term of service is eight years for the first enrolment or ballot, and two or four for the second, when the soldier becomes entitled to an increase of pay. Before the war of independence no one could attain the rank of officer without having been a cadet; and each cadet was bound to prove his nobility. But since the return of Ferdinand these proofs have been dispensed with, and serjeants now obtain a third of the sub-lieutenancies; the other two thirds being reserved for the *élèves* of the military school of Segovia, who have passed the customary examinations at the end of their course of study. The dress and equipment of the Spanish army are in the worst state; the pay of the troops is exceedingly irregular; and their discipline is, in consequence, as bad as it is possible to imagine, or rather, there is scarcely such a thing known.¹ “L’Espagnol, sobre, vigoureux, infatigable,” says Jomini, “possède de grandes vertus guerrières, mais il manque d’activité soutenue. Si dans ces dernières révolutions, son caractère se soumit difficilement à la discipline, nous avons été induit à penser, en observant l’esprit du peuple, que dans les temps ordinaires, il y serait plus facilement ployé. Son courage tumultueux prêtait beaucoup à une prompte désorganisation, car la déroute est toujours compagne de cette disposition naturelle des esprits chez les peuples méridionaux.”² In a word, the Spaniards afford a striking illustration of the truth of Napoléon’s maxim, that *in war the moral is to the physical force as three parts to one*.

After the general peace of 1814, when all the powers of Europe had reduced their military establishment, Portugal alone did not follow their example, but fixed the peace establishment of its permanent army at 49,268 infantry and 5230 cavalry; which, with the militia, made a force of 59,325 men, or about 22 soldiers for every 100 inhabitants. Such a state of things, however, was much too violent to be durable. Accordingly, one of the first cares of the constitutional government of 1821 was to reform a military system so disproportionate to the population and the financial resources of the kingdom. The armed force since that period has therefore consisted exclusively of the permanent army and the militia. The permanent army is composed of a general staff, an engineer corps, 24 infantry regiments of the line of one battalion each, 6 regiments of *chasseurs à pied*, and 12 regiments of *chasseurs à cheval* of 3 squadrons each, 4 regiments of artillery, a battalion of engineer artificers, a company of soldiers of the train, a police guard, and 30 companies of veterans. The general staff consists of an indeterminate number of lieutenant-generals, 16 major-generals, 24 brigadier-generals, 6 superior officers, 6 subalterns, 12 aides-de-camp, 12 secretaries, 10 employés, and a veterinary surgeon-in-chief; in all 100. The engineer corps (*corpo de engenheiros*) is composed of 4 colonels, 4 lieutenant-colonels, 8 majors, 12 captains, 12 lieutenants of the first class, and 12 of the second; in all 64. Each regiment of infantry of the line and of light troops consists of 44 officers and 780 non-commissioned officers and soldiers. The effective strength of a regiment of artillery is 551 men, including 33 officers. The corps of the train of artillery (*artilheiros conductores*), reduced to a single company by the organization of 1821, is composed of 12 officers, 30 soldiers, and 70 mules (*bestas muaras*). The battalion of engineer artificers consists of

¹ *Notice sur l’Armée Espagnole*, rédigée sur *El Estado Militar* de 1828 et sur un manuscrit. Paris, 1829. *Bulletin des Sciences Militaires*, tom. v. p. 420. With regard to the present state of discipline, or rather of indiscipline, of the Spanish army, the author of the *Notice* observes, “La discipline n’a jamais subsisté dans l’armée Espagnole. Ce n’est pas qu’il manque de règlement; il en existe un fort étendu, rédigé avec soin d’après le nôtre (le Français) de 1792; mais c’est un frein qu’on n’a pu jusqu’ici amener l’Espagnol à supporter. Au respect près que le soldat a pour son officier, il n’y a pas l’ombre de discipline.”

² *Histoire Critique et Militaire des Guerres de la Révolution*, tom. i. p. 242.

Army. 201 men, including 12 officers. Each of the 30 companies of veterans is from 70 to 80 strong, including 2 officers. The police guard of Lisbon consists of a battalion of infantry of 8 companies and 980 men, including officers; together with a battalion of *gens d'armes à cheval* 238 strong, divided into 4 companies. The effective force of the permanent army on the peace establishment is therefore 29,645 foot, and 4411 horse. But the events of which Portugal has since 1821 been the theatre, and the circumstance of six battalions having been sent to Brazil, render it probable that, at the period of the insurrection of the Marquis de Chaves, the regular army did not exceed 24,000 or at most 25,000 men. The militia form 48 regiments of infantry, of the same strength and composition as those of the line; together with six separate corps, of which three are infantry, two cavalry, and one artillery; amounting in all to 38,542 men, and, with the army of the line, making the total of land forces 68,187 men of all kinds and arms. The *ordinenzas*, which formed 441 legions or *capitanea mores*, were abolished by the Cortez in 1822, to the great satisfaction of the nation, which justly regarded this institution as a most grievous scourge. They were a sort of levy *en masse*, which all individuals between the age of 16 and 60, unless serving in the regular army or in the militia, might be called upon to join at the shortest notice. The army, which is indebted for its organization to marshal Beresford, is well disciplined and instructed. Its equipment and arms are the same with those of the English troops.¹

Austrian army. At the period when the emperor of Germany engaged in war with revolutionary France, the Austrian army was on a very effective footing, both in regard to organization and numbers. The infantry, it is true, though well trained and disciplined, wanted vivacity, and its physical was superior to its moral force. But the cavalry, which was composed of admirable materials, rivalled the Prussian squadrons in instruction, and surpassed them in other particulars. The artillery and engineers were also good, although the *matériel*, less perfect than that of the French, was either too heavy for pieces in position, or too light for efficient service in the field. Nor was the staff deficient either in erudition or in talents; but its theories were antiquated and vague, resting partly upon the system of cordons attributed to Lascy, and partly also upon certain hypotheses, which it was gravely proposed to put to the test of experiment in the field. At the commencement of the war with France, the imperial army consisted of 232 battalions of infantry and 220 squadrons of cavalry; and as the battalions were very strong, being raised by means of reserves to 1200 men and upwards each, the whole of the Austrian force at this period may be estimated at 240,000 foot, 35,000 horse, and 10,000 artillery.² But the reverses it experienced in consequence of an obstinate adherence to a vicious system, and the exigencies of the long and protracted struggle with republican and imperial France, led to successive augmentations of the effective force, until at one time it considerably exceeded 700,000 men of all arms. At the general peace of 1814, however, Austria, exhausted by a war of five-and-twenty years, reduced her military establishments nearly one half; adjusting the scale of peace so as to render it commensurate with that which,

Army. it was conceived, France would adopt as soon as the Bourbons felt themselves in a condition to re-organize a permanent force. Several changes, indeed, have since been made; but the account which follows, derived from the most authentic sources,³ will be found to exhibit a correct view of the actual force and organization of the Austrian army, consisting of the troops of the line, and the *militär-grünzen*, or *military of the frontiers*.

The *infantry*, exclusive of the 17 regiments of the frontiers, is composed of 58 regiments of the line, 1 regiment of chasseurs, 12 battalions of chasseurs, and 5 garrison battalions; besides, in time of war, the infantry of the staff and the landwehr. Of these, 3 are recruited in Lower and 2 in Upper Austria, 5 in the interior and in the Illyrian provinces, 9 in Bohemia, 5 in Moravia, 11 in Galicia, 4 in the Venetian States, 4 in Lombardy, 12 in Hungary, and 3 in Transylvania. The different regiments are designated respectively by the names of their provinces, and those of the officers who are proprietors therein (*inhaber*). A regiment of the line consists, in time of peace, of a staff, 2 companies of grenadiers, and 18 of fusileers. The companies of fusileers form 3 battalions, each of 6 companies; and 2 companies make a division. In time of war a fourth battalion is organized, called that of the depot, and is composed of 4 companies. The companies of grenadiers form separate battalions, commonly consisting of three divisions or six companies; but there are at present two battalions which have only four companies. The Hungarian and Transylvanian regiments consist, in time of war, of 4 battalions of 6 companies each; and the company contains 200 men. The force of the infantry of the line amounts, therefore, on the peace establishment, to 1044 companies of fusileers and 116 of grenadiers, or 174 battalions of fusileers and 20 of grenadiers; and, during war, to 1134 companies of fusileers, or 189 battalions, and the same number of companies or battalions of grenadiers. By the *military frontiers* are understood the provinces and districts continuous with Turkey, to the east and south of the empire; which, by reason of the military service, internal as well as external, that their male population is subject to, have an organization entirely military; some districts of Transylvania alone excepted. These military provinces furnish 17 regiments of national infantry, a battalion of *tschakists* or watermen of the Danube, and a regiment of hussars (*szekler*), who, in as much as they are liable to be called to join the army, really form part of it, but who, in respect of their particular organization, may be considered, in time of peace, as constituting a distinct force. Military Croatia comprehends six districts, each of them furnishing a regiment, which bears the name of the chief place of the district, and consists of 12 companies. The service of these regiments in time of peace is confined to guarding the cordon. The light infantry is composed of the imperial regiment of Tyrolese chasseurs, consisting of 4 battalions of 4 companies each; and of 12 battalions of chasseurs, 4 companies each in time of peace, and 6, with a *depôt* company, in time of war. A company of chasseurs consists of 195 men, including officers. The garrison battalions, composed of a sort of demi-invalids, unfit for the service of the line, are stationed, 1 in Buckowina, 1 in Esclavonia, 1 in Hungary, 1 in Dalmatia, and 1 in Lom-

¹ Notice sur l'Armée Portugaise, extrait analytique de l'Essai Statistique sur le Royaume de Portugal et d'Algarve, par Adrien Balbi, Paris, 1827. Bulletin des Sciences Militaires, tom. iv. p. 121. Some alterations have, we believe, been introduced by Don Miguel; but we have not been able to ascertain their nature or extent.

² Jomini, Guerres de la Révolution, tom. i. p. 232.

³ The account of the Austrian army, given in the text, is derived partly from the Allgemeine Militär-Zeitung, which appeared at Leipzig and at Darmstadt in 1826, partly from the Constitution de l'Armée Autrichienne of Bergmayr, and partly also from the Annuaire Militaire Autrichien, together with a variety of papers in the Bulletin des Sciences Militaires, tom. iv. v. vi. and vii. 1827, 1828, 1829, and 1830.

Army.

bardly, and consist each of six companies, with the same complement of officers and non-commissioned officers as the companies of the line. The divisions of infantry of the staff (*stabs-infanterie-division*), are composed in the same manner, and organized, in time of war, for the purpose of guarding the head-quarters and the magazines of the army, and of removing the wounded from the field of battle to the nearest hospitals. The number of battalions of the landwehr is seventy. In each district of country (Hungary, Transylvania, and Italy excepted) assigned for the recruitment of a regiment, two battalions of landwehr are raised and attached to such regiment; the one containing the men who are the least necessary to their families, and the most proper for the service, and the other, the surplus of those who are obliged to form part of the landwehr. The first battalion is exercised fifteen days in the year, the second only eight hours. The commandants receive their orders from the colonel of the regiment of the line to which their battalions are respectively attached. The landwehr is principally destined for the service of the interior; but it may also be sent to an active army. In either case it is paid the same as the troops of the line.

The *cavalry* consists of 8 regiments of cuirassiers, 6 of dragoons, 7 of light horse, 11 of hussars (exclusive of the frontier regiment), and 4 of hulans; together with, in time of war, the dragoons of the staff (*stabs-dragonner*); all raised, like the infantry, in different provinces, viz. 3 regiments of cuirassiers in Bohemia, 3 in Moravia, 1 in Lower Austria, and 1 in Central Austria; 3 regiments of dragoons in Moravia, 1 in Upper and Lower Austria, and 1 in Lower and Central Austria; 1 regiment of light horse in Moravia, 4 in Bohemia, 1 in Galicia, and 1 in Italy. The hussars of the 11 regiments are all either Hungarians or Transylvanians. The regiments of hulans consist of inhabitants of Galicia and volunteers. In time of peace, the regiments of cuirassiers and dragoons consist of 6 squadrons, and the other regiments of 8; making in all 260 squadrons. Two squadrons make a division; and, in regiments which have 8 squadrons or 4 divisions, 2 are commanded by the majors. The dragoons of the staff, of which there are several divisions in time of war, have the same destination as the infantry attached to it, and are besides employed in repressing disorders committed by marauders, and in other like services.¹

The *artillery* is divided into three parts, or distinct corps, viz. the field artillery (*feld-artillerie*); the artillery of the arsenals and magazines (*feld-zeugamt*); and garrison artillery (*garnison artillerie*). The *field artillery* consists of a corps of bombardiers, 5 regiments of field artillery, and a corps of fire-masters. The corps of bombardiers has a staff, and 5 companies of 204 men each, including officers. It is recruited by corporals of artillery, and performs the most difficult as well as important service to the army. A regiment of field artillery is composed of a staff and 4 battalions, one of 6 companies and three others of 4 companies each; making in all 18 companies. A company serves three or four batteries of 6 pieces; and each battery is commanded by a lieutenant or major-firemaster. The train of the army furnishes the horsing of the batteries,

which is under the command of officers of that corps, and generally independent of the chiefs of batteries, but subordinate to them in this particular service. The corps of firemasters is established at Neustadt, near Vienna, where it is at present occupied in attempting to fabricate Congreve rockets, we know not with what success. The *artillery of the arsenals and magazines*, consisting of a staff and *personnel* of the necessary workmen, furnishes the field artillery, and the equipages of war, with the requisite arms and munitions, and it guards them when in magazine. The *garrison artillery*, charged with the service in fortresses, is divided into fourteen districts, determined by the provinces, and proportioned in numbers to these districts. The district of garrison artillery of Vienna comprehends an arsenal, containing all the equipage of sieges; and attached to it are a foundery, an establishment for boring cannon, and manufactories of saltpetre and gunpowder.

The *engineer department* comprehends a corps of engineers, with the sappers and miners. The pontoon train is attached to the staff, and is under the direction of an *oberst-schiffamt* or chief of boats. The train or corps of military equipages (*militär-fuhrwesen-corp*s) is wholly independent. The engineer corps is composed of 4 generals, 6 colonels, 9 lieutenant-colonels, 18 majors, 42 captains, 30 captains *en second*, 30 lieutenants, 30 sub-lieutenants, and 12 cadets. Each command or military division embraces a district of fortification; consequently there are fourteen such districts, to each of which is attached a director, who is taken from the generals or officers of the engineer staff. In each place there is also an engineer-in-chief, who is an officer of the staff or a captain of engineers; but in Vienna, Milan, Peterwaradin, and Venice, the director performs the functions of chief engineer. The corps of miners is composed of a staff, five companies, and a garrison detachment; and the corps of sappers, of a staff like that of the miners, six companies, and a garrison detachment. The pontoon corps consists of a staff and 2 battalions of 4 companies each. In time of war the number of battalions is three, two of which have 6 companies and one 4; besides a company in dépôt. The train or corps of military equipages consists, in time of peace, of 12 divisions of transport (*transports-division*), and 20 sets of horses for field batteries (*exercier-batterie-bespannung*). Each division is provided with 90 horses; and all the detachments of the corps stationed in a province are under the orders of a commandant. In time of war the military equipage train consists of seven principal divisions, viz.: 1. the artillery transport division; 2. that of pontoons; 3. that of flying bridges; 4. that of baking; 5. that of health for the transport of the wounded; 6. that of victualling; and, 7. that of general transport.

Two regiments of the same or different arms form a brigade, which is under the orders of a major-general; and two or three brigades form a division, which is commanded by a field-marshal-lieutenant. In time of war, corps d'armée are organized, each consisting of several divisions, and under the orders of a general of cavalry or artillery, or of the oldest field-marshal-lieutenant. In the Austrian army there are at present 10 field-marsals, 18 generals of

¹ Jomini has particularly remarked the superior composition, organization, and discipline of the Austrian cavalry, which has proved its excellence in many bloody encounters, and, when led with talent, has never failed to distinguish itself. At the battle of Würtzburg, 3d September 1796, Wartensleben passed the Maine with twenty-four squadrons of cuirassiers, attacked the French cavalry under Bonnaeu, overthrew it, and thus decided the victory. "This brave veteran," says the Archduke Charles, "impressed with the importance of the order which he had received, dashed into the Maine at the head of his cavalry, and swam across." "This manoeuvre," he adds, "was completely successful: the French cavalry, which had awaited the charge without stirring, was overthrown." At the battle of Leipsic, the Austrian cuirassiers, commanded by Nostitz, "covered themselves with glory." On the 16th October, at one o'clock in the afternoon, Nostitz, having scarcely passed the Pleisse at Gröbern, attacked the lancers and dragoons of the French imperial guard, overthrew them, and then broke several squares of infantry. Other instances of a similar kind might be mentioned.

cavalry and artillery, 67 field-marshal-lieutenants, and 118 major-generals, in actual service; 9 generals of cavalry and artillery, 30 field-marshal-lieutenants, and 92 major-generals, unemployed. The guards form no part of the army. They are divided into the noble body guard of arquebusiers, the Hungarian body guard, the guard called *trabants*, and the civic guard. The military institutions of the first order consist of the company of cadets at Olmutz, that of Gratz, the military academy for cadets at Vienna, the five regimental schools of artillery, the school of bombardiers, and the academy of engineers. The total of the peace establishment of this army is 270,000 infantry and 50,000 cavalry, with a reserve of 250,000; while its war establishment, which can be organized in four months, may be estimated at 750,000 infantry and from 70,000 to 75,000 cavalry.

At the death of Frederick the Great, the army of the Prussian monarchy, amounting to about 200,000 combatants, was accounted the best of Europe. Proud of a struggle without example in modern annals, and of the superiority of the genius of their king, the victors of Leuthen, Rosbach, and Torgau added to this force of opinion an instruction in great manœuvres, which the troops of no other nation approached, much less rivalled.¹ The successor of Frederick, to whom this superb army descended, though possessed neither of his genius nor his ambition, was at great pains to maintain the reputation which it had acquired; and some laurels that had been easily gathered in the Low Countries seem to have inspired him with the notion that it was still capable of equalling, perhaps surpassing, the brilliant achievements which had established its renown. In this spirit, and, doubtless, believing that the French nation might be reduced with the same facility as the insurrection in Holland, the Prussian monarch put himself at the head of the confederacy formed to crush a people who had risen in arms to assert their liberties and preserve the integrity of their territory. But the issue proved how much he was at fault in his calculation. For a mercenary and mechanical army, however perfect its discipline and instruction may be, can never triumph over a generous people, inspired by patriotism, endowed with high military qualities, and resolved to conquer or to die in defence of their liberties. Besides, the Prussian army of this period² was not a national one, nor was it animated by a common feeling. The half of it, as at Frederick's death, was still composed of deserters from all nations, or volunteers enlisted in every circle of the empire;³ it was neither inspired by the genius of its chief, nor excited by any feeling calculated to improve its moral force: discipline formed the only tie by which it was held together. Nor was it long ere its inferiority was proved, and its pride severely humbled. The affair of Valmy opened the king's eyes; and henceforth, more docile to the suggestions of prudence, he negotiated for permission to withdraw to the right bank of the Rhine the wrecks of that army the glory of which had just been eclipsed in the plains of Champagne by

battalions of youthful volunteers. He had been taught a lesson by which he did not fail to profit; and after the unsuccessful campaigns on the Rhine, he sneaked ingloriously out of the contest which he had been so eager to commence; leaving the empire and Austria to the undivided resentment of the conquerors. But he re-established his army, while his late ally was maintaining a death-struggle. The parades and manœuvres of Potsdam were resumed with their wonted éclat; confidence revived; and Frederick began to flatter himself that he alone could re-adjust the disturbed equilibrium of Europe. He failed, however, to observe the prodigious development which the military art had received in the course of the revolutionary war; or at least he neglected to profit by the discoveries to which it had given birth: and, as he had formerly deserted his ally at the beginning of the contest, so now he took the field just at the moment when that same ally was being overthrown at Austerlitz, and compelled to accept the terms dictated by the conqueror. And at Jena as at Auerstadt, at Halle as at Lubec, he paid the price of his procrastinating folly. But misfortune, a rough school-mistress, had inculcated some useful lessons. The military constitution of Prussia was changed; foreign recruitment ceased; a national army was formed; the privileges of the nobles were abridged; old institutions were reformed; discipline was improved by being simplified; the arming and equipment of the army were improved in all their branches; the best parts of the French military system were adopted; the patriotism of the nation was roused; in short, during five years, Prussia was silently but actively employed in preparing those elements of strength which, in 1812, delivered the monarchy from the yoke of the stranger, and re-established her at the head of the second-rate powers of Europe.

The armed force of the Prussian monarchy is composed, first, of a permanent army; secondly, of a war reserve or *landwehr* in two bans; thirdly, of a *landsturm*, or sedentary national guard. The permanent army is composed of young men of family who are destined to the profession of arms, and are named officers after undergoing certain examinations; of volunteers who clothe, equip, and support themselves for a year at their own charge; of persons between the ages of 17 and 40 who enlist voluntarily and receive regular pay; of a part of the youth from 20 to 25 years of age, raised by means of requisition; and, lastly, of veterans or soldiers who consent to remain in the service beyond the term prescribed by the law. The *infantry* consists of 36 regiments of 3 battalions and 9 regiments of 2 battalions, besides six battalions of chasseurs and carabineers, forming in all 132 battalions; the *cavalry*, of 38 regiments of 4 squadrons each, 10 of which are cuirassiers, 5 dragoons, 13 hussars, and 10 hulans, in all 158 squadrons;⁴ the *artillery*, of 9 brigades, each consisting of 3 companies of horse, 12 of foot artillery, and 1 of artificers; and the *gens-d'armes*, of 8 brigades, divided each into 2 detachments.⁵ All the youth who have not served five years

¹ *Guerres de la Révolution*, tom. i. p. 228. Notice sur le Système Militaire de la Prusse, *Bullet. des Scien. Milit.* tom. iii. p. 417, 461, 541, et tom. v. p. 417. See also *Archiv für neuere Kriegs und Armee Geschichte*, vol. i. part 1st, and *Zeitschr. für Kunst, Wissenschaft, und Geschichte des Krieges*, part 2d, 1817.

² At the commencement of the French Revolution the Prussian army consisted of about 120,000 infantry, 35,000 cavalry, and from 7000 to 8000 artillery, with a most respectable corps of engineers. (*Guerres de la Révolution*, i. 232.) In 1806, it amounted to 260,000 men of all arms. (*Etat Comparatif de l'Armée Prussienne en 1806 et en 1827*. *Bullet. des Scien. Milit.* tom. v. p. 417.)

³ Jomini reckons the number of foreigners serving in the Prussian army at this period at only a third part of its entire strength; but we agree with the author of the *Notice sur le Système Militaire de la Prusse* in thinking it amounted to a half. The data on which this conclusion is founded appear amply to warrant the statement made in the text. (*Hist. Crit. et Milit.* i. 233.)

⁴ The Prussian cavalry, in the time of Frederick, was confessedly the best in Europe. "L'infanterie Prussienne," says Jomini, "quoique manœuvrière, était cependant loin d'atteindre le degré de perfection auquel Seidlitz avait porté la cavalerie: cette dernière arme tenait alors le premier rang en Europe." (*Hist. Crit. et Milit.* i. 231. See also *Cavalry Lectures*, p. 329.)

⁵ The gens-d'armes is of three kinds: the *armée gens-d'armes*, divided into detachments stationed at the head-quarters of generals of corps-d'armée; the *land gens-d'armes*, consisting of 80 wachmeister and 1240 gens-d'armes, of whom 1080 are mounted; and the *ganz-gens-d'armes*, which assists the employés of the customs in discharging their duties on the frontiers.

Army. in the active army or in the reserve form part of the *first* ban of the *landwehr*, until they attain the age of 30 years complete. The *second* embraces those from 32 to 40 years of age; and both classes, during time of peace, remain at home, pursuing their ordinary avocations. But, in the event of war, the first ban is destined to reinforce the permanent army; and the second, to form the garrisons of strong places, and even, in case of need, to send detachments to the army in the field. The *landwehr*, like the permanent army, is composed of infantry, cavalry, and artillery. In the year 1827, the infantry of the first ban consisted of 116 battalions, and the cavalry of 104 squadrons. Hence, if we include 54 garrison companies, and 18 of invalids at Berlin, Stolpen, and Rybnik, the total of the peace establishment of the Prussian army will amount to 122,000 men, while that of war would not be less than 250,000 men of all arms: and such is the admirable military organization of the country, that two months only are necessary to raise the army to the full complement of the war establishment. In Prussia the cavalry is a preponderating arm. Of the 122,000 men composing the peace establishment, 37,000 belong to this branch of the service. The *landsturm* is a levy *en masse* of men from the age of 17 to that of 50, and, in cases of imminent danger, it is called out by a royal ordonnance. It is formed into urban and rural companies, and, like the French national guard, performs, if necessary, the duties of the interior; thus leaving the whole of the permanent army and the *landwehr* available for the service of the field. The actual constitution of the Prussian army is strictly economical in all its parts, and the number of military functionaries is reduced to the lowest possible scale consistent with the efficiency of the service. In Prussia every man who wears a uniform works hard for his money.

All Prussians, from the age of 20 to 50, are held liable to military service, but they only serve regularly from 20 to 26. The duration of service is consequently fixed at five years; but, in time of peace, the requisitionary youth remain only the first three years under their colours, after which they return to their homes, and are not called out again, except for a few weeks towards the expiry of the fifth year, when they are inscribed in the *landwehr* of the first ban. The population of Prussia being 11,500,000 souls, about 98,000 males will annually attain the twentieth year of their age. Hence, if we deduct 38,000 for such as are excepted from military service on account of their age or their status in society, the total number of disposable persons, between the age of 20 and 25, will amount to 395,000. And if to this we add that portion of the male population from 25 to 32 years of age who are eventually called to the service, it will follow that Prussia, without having recourse to the second ban of the *landwehr*, could raise 900,000 men trained to the use of arms; while France, even since 1824, when the re-organization of her army commenced, could scarcely bring into the field more than 480,000 men, of which the one half would be nearly untrained in the use of arms. The annual renewal of this army by thirds renders it necessary to push, with the utmost activity, the instruction of both infantry and cavalry, and to pay little regard to that martinet precision which formerly characterized the Prussian tactics, but which is of so small use in the presence of an enemy. The showy parade has consequently been sacrificed to the useful in the field; and the mere foppery of war has given place to movements and evolutions, which are recommended alike by their simplicity, and by the testimony which experience, the best of all instructors, has borne in their favour. So long ago as the year 1808, the degrading discipline, introduced by the father of Frederick the Great, was abolished by the *kriegs-artikel* or the martial law; and military

punishments are now principally confined to hard drills, confinement of various degrees, retrogradation in rank, and some others of a still milder description. Finally, the first grades are the reward of merit established by examination, and as such open to all; while, from the rank of sub-lieutenant to that of general, and even beyond it, seniority, that conservative law of acquired rights, regulates the advancement of officers, and ultimately insures the veteran his reward. Thus, after sustaining the greatest disasters, the Prussian army has survived its dispersion in 1807, and risen, as it were out of its ashes, stronger and better constituted than at the period when it was so rashly opposed to the undivided power of France, wielded by the master-hand of the greatest warrior of modern times. "Heureux les gouvernemens," says a French military writer, "auxquels les malheurs servent de leçons!" Nor would their "happiness" have been much diminished had such governments remembered in victory the promises made to the people in misfortune, and shown but half as much zeal to improve *their* condition as to rectify the defects of their military systems.

At the period of the emperor Alexander's death, the Russian distribution of the Russian and Polish forces was that of an army ranged in order of battle, with its front facing the west. 1. The advanced guard of this army was formed by the Polish army and the corps d'armée of Lithuania; presenting a mass of 80,000 combatants, under the command of the grand duke Constantine. In point of mechanical instruction, no army in Europe could be compared to it. Disposed in cantonments of about 150 leagues in length, from Lowicz to Minsk, and 146 in breadth, between Kowno and Dubno, it could be concentrated, at Warsaw or at Brzecs-Littowsky, in less than three weeks. 2. The army of the right was composed of the corps d'armée, cantoned in Courland and Livonia, of the corps of the guard, and of the first corps of the cavalry of reserve; which, united, formed also a mass of 80,000 combatants. These were perhaps the only troops which, in point of mechanical perfection, rivalled the army of the advanced guard under Constantine. Their cantonments extended from Polangen to Pleskof, about 132 leagues, and from Revel to Wilkomirsz; and eighteen days at the most were sufficient for assembling them on the Niemen. 3. The army of the left, denominated the second army, was equally formed of a mass of 80,000 combatants, cantoned in the Chersonesian governments. The greatest depth of its quarters, from Choczyn on the Pruth to Czerkasy on the Dnieper, was about 106 leagues; and the greatest breadth 180 leagues, between Machnowka, near the southern frontier of Volhynia and Simpherapol in the Crimea. Three weeks were necessary for concentrating it on the Pruth. 4. The army of the centre, called also the first or grand army, formed a mass equal to the three preceding armies, and consequently consisted of 240,000 combatants. Its cantonments extended on one side to more than 234 leagues, or from Kaszin, on the frontier of the government of Tver and of Jaroslaf, as far as Saratow; and, on the other, to upwards of 320 leagues, from Ostrog to Moroum, on the frontier of the government of Vladimir and of Nijei-Novogorod. It required six weeks at least for concentrating itself in the province of Volhynia. 5. Besides these four armies, consisting of 480,000 men, Russia had also several corps, of various descriptions, amounting to more than 267,000 men; viz. the corps of Finland, of Orenburg, and of Siberia, 45,000 strong; the corps of the Caucasus, 85,000; the military colonies, 67,000; and the troops in garrison, 70,000: thus making a grand total of 747,000 men, exclusive of the Kirgishes, Baschkirs, and other Tartar hordes, of whom from 250,000 to 300,000 may in case of exigency be brought into the field. The whole mili-

tary force of the Russian empire, at this period, may, therefore, be estimated at about a million of men, or a forty-ninth part of the entire population; while the country, as we have just seen, was organized into one vast camp, arranged upon strategic principles, so as to render the transition from a state of peace to a state of war easy and expeditious, and, with formidable means of aggression, to combine defensive resources of almost incalculable extent.¹

The contest with Turkey in 1828 and 1829 produced no sensible derangement of this system, and only altered for a time the relative proportions in the numbers of the four principal armies, according as troops were moved upon the various strategic points in the theatre of war. But the *lacune* created by the casualties of the two campaigns in Moldavia, Bulgaria, and Rumelia, have been already filled up; and consequently the above account of the military organization and force of the Russian empire is as applicable in 1831 as it was from the death of Alexander in 1826 to the commencement of the Turkish war in 1828. A fact, however, is mentioned by M. Tolstoy, lately an officer of the Russian staff, which shows the utter groundlessness of the fears generally entertained of the aggressive powers of Russia at the commencement of the late contest with Turkey. From a variety of data, derived from authentic sources, that officer exhibits the situation and force of the Russian army at different periods of the campaign of 1828, and proves, we think to demonstration, that it never had more than 88,000 men in its first line;² a force which was not calculated, certainly, to excite any very great degree of alarm in the minds of other nations. M. Tolstoy, it is true, alleges that political reasons prevented the employment of a greater force; and that if the Russians only brought forward 88,000 men in the first campaign, "c'était qu'ils ne voulaient point effrayer l'Europe et réveiller des jalousies qui sommeillaient." But closer observers will perhaps see reason to believe that the real cause why the campaign was undertaken with a force comparatively so small, did not consist in any particular respect for the "slumbering jealousies" of other nations, but in the inability of Russia to take the field with a larger army; that her physical means are out of all proportion greater than her financial resources or power of developing them in a foreign war; and that, however formidable or invincible she might prove to an enemy invading her own territory, a long period must yet elapse before she can be in a condition to occasion any serious uneasiness to the nations of the south and west of Europe. Even in the campaign of 1829, when so many losses were to be repaired, and the reputation of the Russian arms, if possible, freed from the tarnish they had contracted in the course of the preceding one, Count Diebitsch was compelled to attempt the passage of the Balkan with no more than 30,000 men; and, in point of fact, he appears to have arrived at Adrianople in the month of October, with less than the third of that small force; a miracle of fortune, certainly, but, at the same time, a conclusive proof of the exhausted state of the Russian finances, and of the inability of the czar to carry on a distant and protracted war: Diebitsch owed his success to two causes: the powerful co-operation of the fleet, and the despairing fatalism, or rather infatuation, of the Turks. But the fortunate result of the enterprise cannot blind the world as to the circumstances under which it was undertaken, nor conceal the weakness which preternatural folly, on the part of the Osmanlees, at length gilded with victory.

The Russian *infantry* regiments consist of 3000 men each, under a *pulkovnick* or colonel, and are divided into three battalions of four companies, each under a *chef-de-bataillon*. The company consists of 200 men, exclusive of officers, sub-officers, and other persons attached to it, so that four companies make up a battalion of 1000 men; and it is under the command of a *capitan*, a *parooschick* or lieutenant, a *putparooschick* or sub-lieutenant, and a *praperchick* or ensign. Four officers may appear a small allowance for a company: but, in the first place, Russian soldiers are much more easily managed than our dare-devil fellows, in whose blood the wild spirit of freedom revels so fiercely; and, secondly, the fundamental principle upon which the army of the czar is organized is that of economy in every branch of the service, particularly in the number of officers. Hence, for an effective regular force of 747,000 men, there are no more than 14,224 officers, or one for every 52 men; a proportion, we believe, considerably lower than that which obtains in any other European army, except perhaps that of Prussia. This reduced number, however, has been found to answer well enough in practice; and, indeed, a multitude of officers is only necessary for armies like that of France, which require to be encouraged and stimulated by the example, the voice, and the gestures of its officers, when in presence of an army. Every company has a small green *yaschick* or waggon attached to it, containing sixty rounds of ball cartridge for each man, in addition to those he carries in his pouch, besides the company's books and cash-chest. To each battalion there is attached one standard, beside which is kept a drum for assembling the men. There is only one band for the three battalions composing a regiment. The imperial guard, consisting of the élite of the three arms of infantry, cavalry, and artillery, amounts in all to forty thousand men.³

The Russian *regular cavalry* consists of 8 regiments of the guard, 4 of which are cuirassiers and 4 light horse; and 79 regiments of the line, 9 of which are cuirassiers, 17 dragoons, 12 hussars, and 22 hulans. Supposing each regiment, therefore, to consist of 900 men, as stated by Captain Alexander, the total number of the Russian regular cavalry would amount to 78,000. The *irregular cavalry* is composed of more than 20,000 Cossacks, who are only called out during time of war, and on the return of peace are sent back to their steppes to resume their nomadic course of life. All the regiments of the regular cavalry which are not colonized have 6 active squadrons and one in dépôt; the colonized regiments, though composed of 12 squadrons, have only 6 disposable. The dépôt squadron may be considered the nursery of the regiment to which it belongs. The cavalry is organized upon the same principle as the infantry. It forms, including that of the guard, nine corps d'armée, of 2 divisions each; and as each division consists of 2 brigades, each brigade of 2 regiments, and each regiment of 6 squadrons, every corps d'armée of cavalry consists of 8 regiments or 48 squadrons. Two batteries of horse-artillery are attached to each division, or 48 pieces to a corps d'armée. The light division of the guard is composed of a regiment of dragoons, one of hulans, one of hussars, and one of chasseurs. The division of heavy cavalry of the guard consists of the regiment of chevaliers-guards, of the regiment of horse guards, and of the cuirassiers of the emperor and empress. The two last regiments, as well as the chasseurs

³ Captain Alexander's *Travels*, i. 100.

Army.

of the light division, belong to the young guard. The guard is recruited in the regiments of the line from which it draws all the finest men, and to which it never fails to send back every one who has given the slightest cause for dissatisfaction. The clothing and equipments are superb; and the greatest attention is paid to the appearance of the troops, which has of late years been much improved. Equitation is also anxiously cultivated, and vast pains have been taken to improve the men in this art. But the system pursued in Russia is considered bad, inasmuch as the ambling pace introduced into the schools is apt to spoil the horses, and to produce any thing rather than bold riders.¹

The Russian, like the French, *artillery*, is divided into horse and foot. The horse-artillery is divided into brigades or battalions, of two divisions or squadrons, each serving 12 light pieces. The foot artillery is divided into brigades or regiments, each commanded by four superior officers, and divided into two companies of battery, and two light companies. The two former are destined each to serve 12 pieces in battery; the two latter, 12 light pieces each. A brigade of foot-artillery with 48 pieces of cannon is attached to each division of infantry of 6 regiments; while each division of cavalry, composed of 4 regiments, has a brigade of horse-artillery of 24 pieces. There is also in each corps d'armée a general of artillery, who receives the orders of the inspector-general of artillery. The *personnel* of the companies is determined and organized according to the service which the different kinds of artillery require; so that the *personnel* of the battery companies is considerably stronger than that of the light companies. The train is well organized, and the *attelages* of the different batteries and pieces are ample. The *engineer* department is also on a respectable footing, though inferior in science to those of the other great military nations. The Russians have never been remarkable for skill in fortification, but their field-works have in general been judiciously executed.²

The system of recruiting in Russia is exceedingly autocratical. When new levies are wanted, orders are issued to the headmen of villages; each of which is required to furnish a certain number, according to the amount of its population. The selection is made by the headman, who is perfectly absolute in the matter; and Jews are now obliged either to serve or to pay for substitutes, who are not easily procured in a country like Russia, where so few of the lower class are their own masters. Formerly, it was very difficult to prevent the men from deserting on the road to the depôts; since the circumstance of being selected as a soldier was considered as tantamount to perpetual banishment from family and friends. Hence, it was no uncommon spectacle to see numbers of these wretched serfs fastened together like a cordon of felons going to the hulks, or tied on telegas or carts, and thus conveyed to the depôt. But since leave has been given to soldiers to visit, at intervals, their native villages, and the period of service has been limited to twenty years, the dislike to the army has begun to abate, and recruits show less disposition to desert, although the military profession is still sufficiently unpopular. When the recruit, or rather conscript, arrives at the depôt, he is immediately stripped, washed, and shaved: if he wishes to retain any article of the dress which he brought with him, he is obliged to purchase it back. The only thing he is allowed to retain, without paying for it, is the cross of silver or brass which he wears round his

neck. This, superstition spares him as the only consolation of his miserable existence; and because, however passive in other respects, the most abject serf would become dangerous, if deprived of an emblem which had probably been handed down from father to son for many generations, and the loss of which is considered the greatest misfortune.

The Russian soldier is docile, submissive, and brave: like all slaves, he is supple, subservient, and cunning; like all natives of the northern regions, he is hardy, patient, and enduring. He has no other thought than to do implicitly as he is desired; and there is a pertinacity in his nature which inclines him to persevere, or to stand firm, as the case may be, without troubling himself about consequences. His courage is the result of insensibility rather than of moral force of character; and hence it is commonly more of a passive than of an active character. But there is, nevertheless, an element of indomitable ferocity in his composition: amidst all the apparatus and parade of civilization he is still three parts a barbarian. Hence his most brilliant achievements have been performed under men upon whom the force of civilization had made as little impression as on himself, and whom the instinct of sympathy had taught to develop his natural barbarism. The Italian campaign of Suwaroff affords a striking illustration of this remark. When that "hero, buffoon," arrived in Italy at the head of his 20,000 Russians, to take the command-in-chief of the allied forces, General Chasteler, head of the staff of the army, proposed to him to make a reconnaissance of the French, who had retired behind the Oglio. "Des reconnaissances!" exclaimed the Muscovite chief, "je n'en veux pas; elles ne servent qu'aux gens timides, et pour avertir l'ennemi qu'on arrive; on trouve toujours l'ennemi quand on veut. Des colonnes, la baïonnette, l'arme blanche, attaquer, enfoncer,—voilà mes reconnaissances!" At Novi, at the Trebbia, and during his extraordinary campaign in the mountains of Switzerland, this wonderful barbarian, who had the instinct of genius, and a *coup d'œil* which has never been surpassed, proved that these were not empty words. By a kind of rude but infallible inspiration he discerned intuitively the true strategic points on which to move; and by the spell of his barbaric genius he rendered the Muscovite soldier invincible. Again, in the campaign of 1812, we discover another, though less striking, illustration of this peculiar characteristic of the Russian troops. Barclay de Tolly, a German and a foreigner, commanded in the early part of it; displaying a watchfulness, a prudence, and a sagacity in divining the intentions of his adversary, which proved him a great master in the art of war, and, beyond all question, saved the Russian empire. But still the army was discouraged; and Alexander felt it necessary to place at its head, as well as second in command, two of the ancient companions in arms of the conqueror of Italy. Its courage instantly revived; and the bloody day of Borodino attests how well it repaid this compliance with its wishes. The Russians have a strongly marked national character, which foreigners can never duly appreciate; nor will its best energies be displayed in war, except under the command of men who feel its influence as powerfully as the meanest soldier in its ranks. The moral force of their army consists in a certain nondescript fanatical ferocity, which such men as Suwaroff, Bagration, and Kutusoff can alone fully develop.³

Army.

³ Lieutenant-General Baron Jomini describes the Russian soldier with that predilection in his favour which may not unnaturally be expected from the *aide-de-camp general de S. M. L'Empereur de Russie*, and *grand croix de plusieurs ordres*. But even while he paints *en beau* that infantry "qui avait prouvé à Pultava, à Kunersdorf, à Choczim, à Ismaël, et dans mille actions contre les Turcs

Army. In Sweden, union and confidence have always subsisted between the soldier and the citizen; and hence the desire of military service is so common among all classes of the nation, that sending a man to the army is not there, as elsewhere, a punishment. In 1811, when the peasantry broke out in insurrection against the conscription by ballot, they offered to take arms without exception in the event of war, to submit to be drilled together in time of peace, and to equip themselves at their own charge, provided the obnoxious innovation was abolished; tenders which were wisely accepted on the part of the government. The present military establishment of Sweden is considerably below what a nation constitutionally warlike might be supposed to maintain; but as the aim of the government is to husband the public money, and, if possible, to relieve the country from the pecuniary difficulties entailed upon it by the folly and extravagance of the ex-king, all the departments of the public service have been placed on the most economical footing. The actual standing army, accordingly, does not exceed 35,000 men of all arms. The militia, however, is more numerous; and, from the peculiar aptitude of the Swedes for military exercises, it exhibits a very soldier-like appearance, though only trained for a few weeks annually. Like the regular army, it is composed both of horse and foot, and must afford a ready resource in the event of war. The organization of the whole is excellent. The regiments of the line are recruited neither by voluntary enrolment nor by conscription, but by a kind of intermediate system; every landed proprietor furnishing a certain number of soldiers, to each of whom a house and a portion of land are allotted for his maintenance. The Swedes have been long and justly celebrated for their martial qualities; and no modern nation of so small extent has made so conspicuous a figure in history. They are brave, hardy, and naturally heroic men; of superior physical and corresponding moral power; and, as soldiers, equal to any in the world.¹

Danish army. The Danish army consists of rather more than 30,000 men, with a reserve of about 14,000. Of this force 2157 are divided throughout the kingdom of Denmark, and 9655 stationed in the duchies; while the remainder are employed in garrison, or occupy cantonments in the vicinity of the capital. The whole is composed of a staff of 23 officers; a corps of engineers of 32; an artillery corps of 3202 men, divided into 22 companies; 6126 cavalry, divided into ten regiments, one of which is a regiment of guards; 13,412 infantry, divided into thirteen regiments of two battalions each, one of which is also a regiment of

Army. guards; 2753 chasseurs, divided into five battalions of four companies each; and, lastly, a rocket corps, amounting to 156 men. The two regiments of guards are composed of very fine men, and have a noble appearance. In 1828 the artillery was re-organized, and placed upon a more effective footing, both as to the *matériel* and *personnel*. It now consists of eighteen batteries of eight pieces each; besides a company of sappers and miners, one of pontoon men and pioneers, with a detachment of artificers, and a laboratory establishment. These eighteen batteries are divided into two brigades of nine batteries and 72 guns each. In time of war the battalions of reserve furnish other two brigades, one Danish and the other Holstein; consisting in all of 2640 men, including officers, with a proportional allotment of guns. The Danes are naturally brave, but they have been more distinguished as seamen than as soldiers, in which capacity they have gathered few laurels.²

The electorate of Saxony, with a superficies of 717 Saxon square miles, a population of 2,104,336 souls, and a revenue of about 780,000 thalers, maintained in 1792 an army of about 32,000 men, being a 66th part of the population; and on this footing it remained till 1800, when it was increased to 38,000 men, being a 56th part of the population. But Saxony having in 1802 gained a small increase of territory in consequence of the treaty of Luneville, though, at the same time, it lost about 1,778,000 thalers of revenue, the army was reduced to 31,000 men, of which 22,000 were infantry and 6700 cavalry. This state of things continued until 1806, when the military force was raised to 36,000; Saxony having then a population of 2,276,000 souls. In the year 1809 she furnished a contingent to France of 16,000 men, who, under the command of Bernadotte, the present king of Sweden, took part in the memorable campaign of that year, and fought at the battle of Wagram; but the emperor Napoleon was so little satisfied, either with the conduct of these troops, or that of their leader, on this occasion, that he was with difficulty prevented from stigmatising both in the orders of the day. After the peace of Vienna in 1810, the Saxon army was re-organized upon the model of the French, and its contingent of 16,000 men formed the seventh corps of the grand army which invaded Russia in 1812. It was commanded by General Reynier. On the disastrous termination of the Russian campaign, its wrecks, re-organized from the troops remaining in Saxony, entered into line in 1813, after the battle of Lutzen; and on the conclusion of the armistice with the Hessian corps and that of General Durutte, it formed again the seventh division. The defection of the Saxon divisions at Leipsig,

ou les Suedois, ce qu'on peut attendre de son inébranlable fermeté," he shows his usual discrimination of military character, and makes several observations which appear to us equally striking and original. "L'opinion généralement accréditée en Europe," says he, "que le paysan Russe, ne possédant rien, gagne beaucoup à devenir soldat, est dénuée de fondement. Un grand nombre d'entre eux, outre les champs de ses maîtres, cultive des fruits, des légumes, travaille et trafique à son compte. Beaucoup sont à leur aise; et la vie du soldat dans l'intérieur du pays, ne leur porte pas envie au point de la désirer. Mais quand ce paysan est sous les drapeaux, il s'y attache comme à une seconde patrie.....Élevé de la manière la plus rude, sous un climat terrible, il est le plus robuste de l'Europe, le plus capable de soutenir les fatigues et les privations. Il ne connaît rien de plus sacré que ses devoirs; soumis à l'ordonnance comme aux préceptes de sa religion, aucune fatigue, aucune intempérie, ne peut lui faire négliger les obligations qu'elle impose. On voit dans toutes les marches et durant une campagne entière, le canonier près de sa pièce, au poste qui lui est assigné par le règlement, et à moins d'être frappé par le fer ennemi ou autorisé par son chef, il ne la quitterait pour rien au monde. Le soldat du train cire son harnais au bivouac par 15 degrés de froid et au jour fixé, comme il le ferait dans un bon cantonnement pour aller à une parade. Cet esprit admirable d'ordre et de précision, joint à l'instinct naturel que le soldat a de se pelotonner au lieu de fuir quand il est enfoncé, rend les défaites extrêmement rares. Sans doute, une telle troupe est moins facile à rallier sur le terrain qu'une armée Française, où l'intelligence du soldat supplée souvent au défaut d'ordre; mais elle est aussi plus difficile à rompre.....Cet instinct qu'aucune des troupes de l'Europe ne possède au même degré, s'est fortifié chez les Russes par les guerres contre les Turcs. Là, tout fuyard est sabré par les nuées de cavaliers qui se répandent sur les flancs et les derrières de l'armée. Ce n'est qu'en restant fermes et réunies qu'on échappe à une destruction inévitable. This is a tolerably good reason for the "instinct" of which the gallant author speaks. He adds, "La plus parfaite égalité règne dans l'armée, car une fois dans la carrière des armes, aucun obstacle n'empêche de la parcourir. Pour s'en convaincre, on n'a qu'à voir les noms des généraux distingués dans l'histoire militaire de Russie; on y trouvera autant de plébéiens, ou de bas-officiers parvenus par leur mérite, que dans tout autre pays." (*Guerres de la Révolution*, on i. p. 254-256.)

Army.

on the 18th of October 1813, is known to every body. The king of Saxony having lost his liberty in consequence of the result of that disastrous day, his army was dissolved and replaced by a landwehr of from 10,000 to 12,000 men, which followed in the train of the allied armies when they invaded France. In 1815, however, the army was reconstituted to the extent of a third of its former strength; and underwent various changes until 1824, when it was finally placed on the footing on which it now stands. The *infantry* at present consists of two companies of grenadier guards of 100 men each, four regiments of infantry of three battalions each, two battalions of light infantry, one battalion of carabineers and one of chasseurs; in all sixteen battalions, of four companies each, or 9984 men. The *cavalry*, which formerly consisted of horse guards, cuirassiers, hulans, and hussars, has been transformed into four regiments of light horse, consisting of four squadrons of two companies each, or 467 men, on the footing of peace; in all 1872. The *artillery* consists of one regiment making twelve companies, two of which are horse, amounting to 1060 sub-officers and soldiers, together with a train of 189 men and as many horses. A dozen officers without troops, and a company of sappers 67 strong, compose the *engineer* department. The institutions connected with the army are a school for cadets, and a military academy, both at Dresden. The reputation of the Saxon infantry is low; but the cavalry is better than the infantry, and is well qualified for the service of the advanced posts, which was its usual destination under Napoleon.¹

Hanoverian army.

The composition of the Hanoverian army was fixed by a royal decree of the 14th July 1820. The *infantry* consists of twelve regiments of two battalions each, and the battalion is divided into four companies. There are two of these regiments guards; and the whole are divided into three brigades, the first consisting of five regiments, the second of four, and the third of three. Each regiment consists of 42 officers and 1284 men. There are eight regiments of *cavalry*, two of cuirassiers of the guard, four of hussars, and two of hulans; and each regiment is composed of four squadrons, 48 officers, 433 men, and 403 horses. The *artillery* consists of one regiment of two battalions, each divided into three companies, one of which is horse, and contains 70 officers, 1158 men, and 210 horses. The corps of *engineers* and artificers consists of 19 officers and 46 men. The artillery is of the English model and calibre, and its batteries, both horse and foot, consist of six pieces and a howitzer each. The total strength of the army, therefore, including the staff, amounts to 825 officers, 20,091 men, and 3431 horse. The period of service in the infantry of the guard is four years only, but in all the other corps six years. The cavalry and artillery are recruited as much as possible from volunteers. The Hanoverians make excellent soldiers; and it is well known that, during the Peninsular campaigns, no part of the Duke of Wellington's army more frequently distinguished itself than the King's German Legion, which was almost exclusively composed of Hanoverian volunteers.²

Bavarian army.

The Bavarian is one of the largest of the third rate armies. Its *infantry* consists of a regiment of grenadiers of the guard in three battalions, of 16 regiments of the line in two, and of two battalions of chasseurs; presenting an effective force of 37 battalions, or 43,561 men. Its *cavalry* is composed of a regiment of *gardes du corps*, two regi-

ments of cuirassiers in four squadrons each, and six regiments of light horse in six squadrons; forming a total of 48 squadrons, or 9549 men, and 6000 horse. The *artillery corps*, commanded by a lieutenant-general, consists of one regiment of cannoneers of four battalions, one battalion of train in four divisions, and four companies of artificers, pontoneers, sappers, and miners. Each battalion of artillery is divided into six companies, one of which consists of light troops; and the companies of pontoneers, miners, and sappers, have each an effective force of 100 men, including officers. The *engineer corps* is composed of a general, a colonel, a lieutenant-colonel, two majors, two captains, eight lieutenants of the first class, eight of the second, and six conductors, and is divided among the five directions of Munich, Augsburg, Nuremberg, Würzburg, and Lindau. The Bavarian army, therefore, consists of 43,561 infantry, 9547 cavalry, 3515 artillery, 1464 train, and 150 artificers; in all 56,919 men, with 6420 horse. Every Bavarian, the clergy only excepted, is obliged to bear arms in defence of his country; but, in practice, students and persons necessary to their families are usually exempted; and permission is likewise granted to serve by substitute. The method of recruitment is conscription. Besides the permanent army, there is a reserve destined to reinforce it; and, in the event of war, the landwehr may be equally called upon to support the army, when reinforced by the battalions of the reserve, but only in the interior. The *landwehr* is divided into two classes, one of which comprehends those who are least capable of performing active service, and who cannot in any case be employed beyond the limits of their district. In time of peace it co-operates in the maintenance of public tranquillity, when put in requisition for that purpose, and when the troops of the line are deemed insufficient. The Bavarian army is well organized, and has always maintained a respectable character for discipline and bravery. The cavalry is considered superior to the infantry.³

The small army of Wurtemberg requires only a brief notice. Its *infantry* consists of 8 regiments of 2 battalions, divided each into 4 companies; its *cavalry*, of a squadron of guards, a squadron of chasseurs, and 4 regiments of horse, each divided into 4 squadrons; its *artillery*, of a regiment of 6 companies, 3 horse and 3 foot, besides a garrison company: but it has no engineer corps distinct from that of the artillery. Its peace establishment is composed of 368 officers, 1504 sub-officers, and 5184 soldiers; or 6996 combatants, and 1806 horse: on a war footing it would amount to 520 officers, 2302 sub-officers, and 14,508 soldiers, or 17,330 combatants, and 5228 horse. The Wurtemberg army is recruited by voluntary enrolment and forced levies. The military age is from 18 to 30 for enrolment, and from 20 to 25 for levies; and, in both cases, the élite of the population only is taken. This little army is well-officered, and enjoys some consideration. Count Bismark, the able author of *Lectures on Cavalry Tactics*, is colonel of the 3d regiment of Wurtemberg horse, and served with distinction as general of brigade in Napoleon's Russian campaign.⁴—The grand duchy of Baden, the seventh state of the Germanic confederation, has a superficies of 279 square miles, with a population of 1,108,000 souls, and supports a military establishment of 12,433 men, although it is only bound to furnish a division of 10,000 men (the 2d of the third corps) as its contingent.⁵

Army.
Army of
the Ger-
man con-
federation

The organic law of the military constitution of the Germanic confederation, adopted on the 9th April 1821, in the fifteenth full sitting of the diet, and forming the basis on which the federal army has been organized, is exceedingly complex, and altogether unsuited to analysis within the space which the limits of this article afford. Its leading provisions, however, may be shortly stated, and are as follow:—The army of the confederation is composed of the contingents of all the states members thereof, raised according to the formation of their particular *matricule* or computation in the diet. The proportion of the different arms is regulated conformably to the principles of the new tactics. The federal army is formed of corps d'armée of a single nation or of combined corps, and both are subdivided into divisions, brigades, and regiments. No state of the confederation, whose contingent forms one or more corps d'armée, can combine contingents of other states with its own in the same division; and the states which have corps or divisions combined, concert together the manner of forming and organizing them, and in case of dispute the diet decides. In the organization of the federal army regard is had to the interest resulting from the particular relations of different states, in as far as can be done consistently with the general object of the confederation; and as the rights and duties of all the confederate states are the same, it is specially provided that every appearance of supremacy on the part of one state over another is to be avoided. The contingent of each state must always be completely equipped and ready to take the field as soon as it shall be called to do so; but the force and assembling of the army to be raised, as well as of the reserve, are regulated by particular dispositions of the diet. 1. The ordinary contingent of each state is one hundredth part of its population, conformably to a table prepared and rectified from time to time by the diet. 2. The proportion of the cavalry of the federal army is fixed at one seventh of the total of the troops; and two field-pieces are required for every 2000 men of the contingent, besides one for every 1000 of the reserve in arsenal. 3. The federal army consists of 10 corps d'armée, 7 simple and 3 combined, designed in the order of the digits or primary numbers; and every corps has at least 2 divisions, each division at least 2 brigades, each brigade at least 2 regiments, each regiment of infantry at least 2 battalions of 800 men each, and each regiment of cavalry at least 4 squadrons of 140 men each. The *minimum* of a contingent of cavalry is 300 horse, of infantry 400 men, and of artillery a battery of six or eight pieces. 4. As the contingent of each state must be ready to take the field in a month after it is called upon, all the *matériel* of armament and provisions necessary for the contingent must be deposited in the arsenals of each state, and all the contingents of the army must be kept up to their full complement even in time of peace. 5. The generalissimo of the confederation is chosen by the diet in ordinary assembly, and his functions cease when the federal army is dissolved. 6. The commanders of the corps of every nation or state have the rights which the sovereign whose troops they command may think proper to confer upon them, without deviating from the principles upon which the military constitution is founded. There is a great number of other dispositions and regulations, touching a variety of matters; but those above specified are the principal, and may serve to convey an idea of the military constitution of this great confederacy, organized in imitation of that which, while it seemed to strengthen the hands of Napoleon, proved eventually, by the defection of its members, one of the chief causes of accelerating his fall.¹

lands
army.

The military power of the United Provinces dates its commencement from the middle of the fifteenth century, when, after a long and sanguinary struggle, they succeeded in emancipating themselves from the yoke of Spain; and, in the following century it received considerable development in consequence of the wars which they had to maintain against Louis XIV. In 1702 they had in their pay upwards of 100,000 men, exclusive of 30,000 who were in the service of the Dutch East India Company. But this period may be regarded as the highest condition of the army of Holland, which subsequently declined both in number and reputation; so that in 1775 it did not exceed 30,000 men, fully one third of whom were foreigners. In 1789, Holland, with a population of 2,340,000 souls, inhabiting a country of 625 square miles, supported an army of 36,000 men, consisting of 40 regiments of infantry and 10 of cavalry; and with this force it joined the first coalition against the French republic. In 1792 the Dutch army had been increased to 39,000 infantry, 3450 cavalry, 1560 artillery, and 260 miners and pontoneers; making a total of 44,270 combatants. But in the campaigns of 1793 and 1794 they afforded the Prince of Orange occasion for displaying considerable military talents, put his army to a decisive test, and impressed all with a conviction that its degeneracy in moral force was equalled only by the radical defects of its organization. The conquest of Holland by the French, however, was followed, in 1795, by the reorganization of the army on new bases; and so great was the effect of the changes thus introduced, that the Batavian troops, led by Dumonceau and Daendels, rivalled the French, by whose side they fought, both in discipline and valour, and at Alknaër, on the Rednitz, and on the Danube, bravely upheld the ancient reputation of the Dutch arms. At the peace of 1815, Belgium having been united to Holland in order to form a constitutional monarchy, and England having restored the greater part of the Dutch colonies which had fallen into its hands during the republican and imperial regime, the new kingdom of the Netherlands at once, and as it were *per saltum*, took its place among states of the second order, with a continental superficies of 1165 square miles, and a population of 6,166,854; and lost no time in organizing a military system suited to its position and rank among the nations of Europe. This system rests on a permanent army of about 50,000 men on the footing of peace, and 82,000 on that of war; with an eventual army of national guards estimated at 40,000 during peace, and 124,000 on a war establishment. The kingdom is divided into 6 great and 17 provincial commands, 6 directions of artillery and engineers, and 50 cantons for the levy of the militia and the organization of the national guard. The great commands are confided to lieutenant-generals, the provincial commands to major-generals, the directions of artillery and engineers to general officers, and the militia cantons to old officers of a superior grade. The *infantry* consists of 18 divisions of 4 battalions from 3 to 6 companies each, with a *dépôt* company; the *cavalry*, of 9 regiments 4 squadrons each, of which 4 are cuirassiers, 2 light dragoons, 2 hussars, and 1 lancers; the *artillery*, of 10 battalions, 4 of the line and 6 of the militia, each of 6 companies, a corps of light artillery, and a battalion of the train; and the *engineers*, of a battalion of miners, sappers, and pontoneers. There is also included in the army a colonial *dépôt*, to which are attached 2 correctional divisions, 5 garrison companies one of them artillery, and 9 companies of *maréchaussée*, stationed in the southern provinces of the kingdom. The army of the Netherlands is recruited exclusively from the natives of the country, first, by voluntary enrolments;

Army.

secondly, by engagements and re-engagements for two, four, and six years, with a bounty; thirdly, by calling out the whole or part of the militia; and, lastly, by the recall of men absent on leave, or by having recourse to the reserve. The militia is composed of youth between the ages of 19 and 23, and draughts are made every year in the month of March, in the presence of the commissaries of militia and the local authorities. Advancement is principally regulated by seniority; but every soldier distinguished for intelligence and good conduct may aspire to the rank of officer. The army of the Netherlands has still a character to make for itself. As a national force it has never as yet been put to the test. But it has been organized with great care, and unless political dissensions interfere to destroy its *morale*, there can be little doubt that it will conduct itself respectably when called to serve in the field. The Belgian troops, it is true, behaved ill at Waterloo; but they were evidently disaffected to the cause for which they were called to fight.¹

Sardinian
and Neapo-
litan
armies.

The kingdom of Sardinia, containing a superficies of 1363 square miles, and a population of 4,334,000 souls,² supports an army of about 31,000 men on its peace establishment, and 62,000 during war, exclusive of militia. The permanent army consists of the household troops, the royal guard, the troops of the line, and the carabinieri. The household troops consist of four companies of horse-guards, called the Savoyard, the Piedmontese, the Sardinian, and the Genoese. The royal guard is composed of a brigade of grenadiers, and a regiment of *chassours à pied*, of the same composition and force as a regiment of the line. The *infantry* of the line consists of 9 brigades of 2 battalions each in time of peace, and 4 during war; the *cavalry*, of one regiment of dragoons, two of light horse, and one of the line, each consisting of 8 squadrons or 4 divisions. The carabinieri amount to 3100 men, including officers and 100 élèves, and form a sort of nursery for the army. Since the 3d January 1823, the corps of *artillery* has consisted of 4 battalions, of which 2 are of the line, 1 light artillery, and 1 partly garrison artillery and partly artillery of the train. The royal corps of *engineers* is composed of a supreme council, a staff, a company of miners, and some sappers. At the beginning of the French revolution, the Sardinian army amounted to 30,000 infantry, 3600 cavalry, and upwards of 2000 artillery and engineers. In the year 1815, its total force, exclusive of the royal guard, was not less than 70,000 men. "La Piémontais," says Jomini, "est un excellent soldat; la service des régimens provinciaux a familiarisé toute la nation avec les armes; la peuple, comme la plupart des habitans des montagnes, est frugal, endurci à la fatigue, et brave."³ But the cavalry is much inferior to the infantry; for the horses are bad, and the men ill adapted by habit and character to this branch of the service.⁴—The Neapolitan army is

scarcely deserving of notice, either in a political or military point of view; for, next to the soldiers of his Holiness the Pope, those of Naples are beyond all dispute the worst in Europe. In 1792 the Neapolitan army amounted to 30,000 troops of the line, as they were called, and 15,000 militia; a force which was increased, in 1799, to 60,000 men of all arms; 40,000 of whom invaded the Roman states during the campaign of that year, and conducted themselves rather like banditti than a regular army. Formidable only to its allies, and to the country which it serves to retain in abject servitude, this army has since experienced the most violent mutations; but its number at present may be estimated at from 35,000 to 40,000 men of all arms.

At the period when the Ottomans first became formidable to Europe, they may be said to have composed one army. Every Osmanlee was a soldier, and from the age of sixteen to sixty held himself at the disposal of the state; whilst all were animated with a martial fanaticism, which in fact constituted the main sinew of their strength. They were brave, ardent, enterprising; and if their services in the common cause (which they could not withhold as long as they were able to bear arms) remained unpaid, they were not unrequited. A third of the conquered land was distributed amongst them, and held on the tenure of military service; the peasantry cultivated the fields thus ceded to the soldiery, and paid the rents to their military landlords; and the holders of the *ziamets* and *timars*, or greater and lesser grants, received from the fund of conquest rewards proportioned to their services. But this system, although it placed a large numerical force at the disposal of the chief, was nevertheless attended with serious inconveniences. It created a sort of feudal militia, but was incompatible with the existence of a permanent force; it supplied means for a short expedition or campaign, but a continued series of operations was constantly liable to be paralyzed by the soldiers returning to their homes while these were still in progress. To obviate this evil, it was resolved to raise a body of mercenaries, whose services should be at all times available. Accordingly, sultan Amurath, at the suggestion of his vizier, claimed as his right the fifth part of the Christian youth captured in Bulgaria, Albania, Servia, and Bosnia; who, being instructed in the law of the prophet, and inured to arms, formed a body of soldiers totally distinct from those liable to serve in virtue of their military holdings, and unconnected with the rest of the empire by the ties either of birth or of kindred. Such was the origin of the janissaries. Organized into a regular force, at a time when the armies of Christian powers consisted of a disorderly militia, and uniting courage and enthusiasm with a species of discipline, and a blind obedience to the will of their commanders, this powerful body swept all before them, and spread far and wide the terror of the Ottoman arms. Nor did the splendour

¹ Notice sur l'Armée Néerlandaise: Extrait d'un ouvrage inédit de MM. Urbain et Geenhender, capitaines Néerlandais. *Bulletin de Sciences Milit.* tom. viii. p. 1, 81. The above account of the Netherlands army was written before the revolutionary convulsions in Belgium had effected the separation of that country from Holland; but we allow it to remain unaltered, because, finding it impossible to tell what now is, we have judged it best to leave the reader to infer what may be from that which has recently been, and to form an estimate for himself of the military force of each of these countries separately, from that which was either organized or capable of being brought into the field under their federative union.

² On the continent Sardinia has only 918 square miles of territory, and 3,839,000 souls. The *terra firma* of this kingdom, situated between Switzerland, France, and Italy, forms, on the side of the last-mentioned country, a great basin, which the principal chain of the Alps separates from Savoy, the department of the Isère, and the county of Nice. It may be considered a vast entrenched camp, having, on the side of France, Savoy and the county of Nice as advanced posts. In fact, these transalpine provinces have a free communication with each other only by the plain of Piedmont, where the debouchés from Savoy are by the Great and Little St Bernard, and from the county of Nice by the Col di Tende and the route of La Corniche. This position, which constitutes the king of Sardinia the natural guardian, or porter of the Alps, as he has been called, causes his alliance to be eagerly sought for both by France and by Austria, particularly the latter, who, conscious that her hold of Italy is by no means firm, has an interest in raising up every obstacle to prevent France, in the event of a war, from attacking her on her weakest side.

Army. of their achievements suffer any eclipse as long as Christian captives could be obtained to fill the vacancies in their ranks. But when the janissaries ceased to form a class distinct from the great mass of the nation; when they were allowed to marry and enrol their children; and when the *odas* or regiments became encumbered with men who preferred inglorious ease in the bosom of their families to the toils and dangers of the battle-field; they at the same time ceased to be formidable to their enemies, and, like the prætorian cohorts of ancient Rome, were dreaded only by their emperors. They could raise an insurrection in the capital, demand the head of an obnoxious vizier, and depose or murder an unpopular sultan; but "the yellow-haired Giaours" had learned to despise them in the field; and, in their degeneracy, they seemed destined to accelerate the ruin of that empire which, in their better days, they had contributed so largely to extend and consolidate.

On this class of men, however, did the Porte, until recently, depend in a great measure for defence against her enemies; and although their inefficiency was daily becoming more apparent, and reform more necessary, every attempt to effect a change of system, and regenerate these Osmanlee prætorians, had proved either abortive or disastrous. In vain did Selim try to remodel them, and restore discipline. The attempt cost him his life. In vain did Mahmoud, on his accession, manifest an intention to enforce the regulations of Suleiman the Magnificent. An insurrection was the consequence. During three days the streets of the capital ran with blood; and the sultan, in order to save his own life, was obliged to command the execution of his brother. But Mahmoud was not of a disposition to be daunted by this failure, although it induced him to change his mode of proceeding. He now saw that nothing less than the complete destruction of the janissaries would enable him to improve the condition of his empire, by carrying through the reforms which he already meditated; and he waited patiently until he could strike the blow with a certainty of success. In 1826, the janissaries, who perceived the storm gathering, again mutinied. But it was now too late. They found the sultan prepared for them; and, in raising the cry of insurrection, they only gave the signal for their own destruction. The artillery-men and other troops, faithful to Mahmoud, surrounded them in the Etmeidan: they attempted to defend themselves, but without success: 20,000 perished in the conflict: and the janissaries as a body were from that moment annihilated. This achievement, though accomplished at a terrible sacrifice of life, was in reality an act of humanity as well as of sound policy; and, viewed in its proper light, it reflects equal honour on the wisdom and firmness of the sultan, who planned so judiciously and executed so vigorously a measure full of peril in itself, yet absolutely indispensable as a preliminary step to improvement of any kind.

The suppression of the corps of janissaries having left Mahmoud at liberty to remodel his army conformably to the principles of European science and tactics, he hastened to supply the void occasioned by the destruction of the force to which the country had hitherto trusted for its defence; and orders were immediately issued directing the enrolment of a certain number of men in every province of the empire, excepting Albania, Bosnia, and the African states. But the sultan experienced greater difficulty in raising new troops than he had probably anticipated; for,

Army. although the law which places the services of every Moslem at the disposal of the sultan existed in full force, it applied only to a state of war; and on no previous occasion had such a system of enrolment been resorted to during time of peace; a circumstance which rendered it exceedingly obnoxious to the populace. Another obstacle to the speedy reconstruction of the army consisted in the necessity of excluding from the new corps all persons suspected of what may be called *janissarism*; and as it had been customary for every Moslem, on attaining the age of manhood, to inscribe his name in some *oda* or regiment of janissaries, the only method by which Mahmoud could hope to secure his troops from the contamination of that proscribed sect was by enrolling none but boys in his army. But the adoption of such a plan necessarily created a proportionate difficulty in filling the ranks; while, to add to the embarrassments of the Ottoman reformer, the new system had scarcely been twelve months in operation when Russia declared war against the Porte. That this was a politic proceeding on the part of the Muscovite government, no one can doubt. Mahmoud was caught in the very act of transition from a bad system to a better one; the regiments of the Ottoman army were still incomplete; and the unpopularity of the contest, with a dread of the Russian arms, acted as an additional check to enlistment, and thus aggravated the evils with which the sultan had to contend. The new troops were, however, brought into action. They were as yet too ignorant of the advantages of discipline to benefit by the instructions they had received; their manœuvres served but to confuse them; the officers were superior to the men only in name, and the generals were equally destitute of talent; the interior organization of the army was lamentably defective; and the troops had but little confidence either in their officers or in themselves. Yet, with all these disadvantages, the first campaign terminated favourably for the Turks; and it cannot reasonably be doubted that the second one (that of 1829), would have had a similar result, if the Osmanlees had been commanded by a man possessed even of ordinary military talents and enterprise. The grand vizier was unquestionably a brave man; and, unlike Yusuff Pasha, he was faithful as well as brave. But, with 40,000 regular troops, superior to any that the Porte had ever sent into the field, he allowed himself to be surprised at Kiulewtscha or Kuletscha, and, having lost more than the half of his force, was compelled to retire to Shumla with the remainder. The succeeding events of the campaign were the natural corollaries of this disastrous battle: But without dwelling upon these, which are foreign to the objects of the present article, we shall proceed to give some account of the Ottoman army as it is at present constituted.¹

The Ottoman army is composed of regular and irregular infantry and cavalry, a corps of artillery, and a regiment of bombardiers or miners. The *Assakiri Mansurei Mohamediyes*,² or regular infantry, are said to amount to 50,000 men, of whom 10,000 compose the imperial guard, quartered in and around Constantinople. They are recruited from the mass of the people without distinction; and although Mahmoud did not oblige the children of his nobility to enter into the service, yet, at the beginning of the late war, many enlisted voluntarily, and even some of the Ulemas, or expounders of the law, forsook their peaceful profession and enrolled themselves. The black and white

¹ Trant's *Narrative of a Journey through Greece* in 1830, p. 364, *et seqq.* We take this opportunity of acknowledging our obligations to Captain Trant's work for a very considerable portion of the details respecting Sultan Mahmoud's military reforms, as well as the present condition and strength of the Ottoman army. There are many points, in regard to which it could have been wished that Captain Trant had been somewhat more specific; but on a subject where exact information was not easily attainable, military men ought to be grateful for what this respectable officer has been able to collect concerning it.

² Literally, "victorious troops of Mohammed."

Army.

subjects of the sultan are alike received as soldiers; and, in a single regiment, may be seen every shade of "the human face divine," from the jet-black complexion of the Ethiopian or Nubian to the white-visaged inhabitant of Rumelia.¹ Once enrolled, a soldier is obliged to serve for life; but it frequently happens that discharges are granted. The regular troops are organized on the model of the French army, and are divided into corps d'armée, divisions, brigades, and regiments. The corps d'armée is commanded by a seraskier, the division by a pasha of three tails, the brigade by a pasha of two tails, the regiment by a miri-alay or colonel, and the battalion by a bimbashée or chef de bataillon. A regiment consists of a regimental staff (including the miri-alay or colonel, the caimaçan miri-alay or lieutenant-colonel, and the alay-emin or major) and three battalions, each composed of one bimbashée or chef de bataillon, one sagh-col-aghassy or adjutant-major, one sol-col-aghassy or adjutant, 8 yuzbashees or captains, 16 mulazims or lieutenants, 32 tchiaouchies or serjeants, 48 on-bashees or corporals, and 720 men; making a total of 2484 officers and soldiers, exclusive of a drum-major, an imaum or chaplain, and a kiatip or clerk. The inveterate prejudices of the Moslems against the employment of European officers in the service have prevented Mahmoud from placing any foreigners in command of his troops; and these have hitherto been disciplined, partly by officers who had served under Selim in the Nizam Djedid, partly by persons sent from the Egyptian army. The only footing on which the Turks will consent to tolerate an European officer is as an instructor; and in this capacity Signor Calosso, a ci-devant captain of dragoons in the Italian army of prince Eugene Beauharnois, has been employed by the sultan to superintend the discipline of his cavalry. But the infantry have not been equally fortunate, and are consequently labouring under very great disadvantages. The officers, taken from the same class of society with the common soldiers, differ from them in nothing but rank and name: in the Turkish army there is no one to look up to, no natural aristocracy created by superiority of condition and of knowledge: the same ignorance and the same prejudices pervade all ranks; and, having the benefit neither of examples nor of models, their progress in discipline has been necessarily slow. The Turks seem to think that performing the manual and platoon exercises with tolerable precision, marching in companies instead of independently, and wearing a peculiar uniform, is sufficient to class them with disciplined troops. But, in their anxiety to attain the end desired, they have overlooked some of the most essential means. The soldier, for example, is placed in the ranks before he knows how to march; and provided he goes through the manual and platoon exercises, it matters not whether his carriage be steady or the reverse. When in the ranks, the men talk and laugh without restraint, and even address themselves to their officers; whilst the latter, instead of checking, encourage these improprieties, by joining in or retorting the rude ribaldry of the troops. Field-officers are indeed treated with the most obsequious respect by their inferiors; but the line which has been drawn betwixt the privates and subaltern officers is by no means sufficiently distinct; and it is easy to perceive throughout, that the hand of a master is wanting to combine all the elements of discipline, which are now but imperfectly understood, and to impress upon the higher ranks the necessity of studying

their profession, in order to qualify them for discharging the duties of command, as well as to ensure the respect and obedience of the troops.

The Turkish *cavalry* had so long been celebrated for its gallantry and enterprise, that the policy of remodelling it seems exceedingly questionable. This, however, has been attempted, though, as it appears, with very indifferent success. Four squadrons of dragoons are attached to the guard, and compose the only regular cavalry in the empire. These are mounted and equipped in the European fashion; but the horses are small in size, ill-conditioned, and badly groomed;² and the men find so great difficulty in accommodating themselves to the European method of riding with long stirrups, that their seat is loose and ungraceful, and they are not unfrequently thrown from their saddles, to their own infinite mortification. The scimitar, so effective in the hand of a Turk when mounted in the fashion of his country, has also been exchanged for the French light dragoon sabre; a weapon so differently balanced from that which the Osmanlees have long been accustomed to handle, that they are not likely soon to acquire much dexterity in the use of it. These changes, in fact, seem the very wantonness of innovation; for whilst they have destroyed all that is national or characteristic in this description of force, they have substituted nothing effective in its stead; and Mahmoud will probably find to his cost that he has sacrificed a superb light cavalry for wretched dragoons. His policy should have been, to leave to the Turks their national horsemanship and their national weapons, and to direct his attention exclusively to field tactics and manœuvres, in order to give unity and effect to those daring charges which they are so admirably fitted to execute effectively in their own way. Without firmness in their saddles or confidence in their weapons, the new troops may make a tolerable appearance on parade; but if sent into the field, they will, in all probability, be found unable to contend with the worst description of horse to which they may be opposed.

The *artillery* is of two kinds, viz. foot and horse. The topejees or foot artillery are said to be at present 6500 strong; and although their new organization has not taken place, it is understood to be the intention of the sultan to form them as soon as possible into regiments. The horse-artillery, though in a very inefficient state compared with ours, has made considerable progress in discipline. It is divided into two regiments of four troops each; and every troop consists of one captain, three subalterns, 180 men, 180 horse, and 10 guns; thus making the total effective strength of a regiment 786 men, 720 horses, and 40 guns, which are commonly nine-pounders and five-and-a-half-inch howitzers. The officers are supplied with horses by the government; and the forage allowed to each horse is nine pounds of barley and twelve pounds of chopped straw *per diem*. The corps of bombardiers and miners amounts to about 2000 men; but they are still quite undisciplined, and as ignorant of the scientific as they are negligent of the practical part of their profession; their gun carriages, platforms, and ammunition waggons, being in a shameful state, and totally unfit for service. The education of artillery officers has hitherto been entirely neglected; but a college has recently been established for their instruction in the theory and practice of gunnery.

The irregular army may be said to comprise the whole

¹ "Ah!" said a janissary to Captain Trant, while observing a body of troops marching past, "what kind of soldiers are these? You see every race and every colour on earth amongst them!" Granted; but martial qualities are not necessarily connected with colour; and discipline, if rigorously enforced, will in time mould even these variegated elements into a fine and formidable army.

² This may seem singular, considering the ideas generally entertained of Turkish horses: but, in the first place, these are very much exaggerated; and, secondly, the government were obliged to purchase horses wherever they could be found—in Asia, Rumelia, and Wallachia. The best horses belong to the irregular cavalry.

Any. Mahommedan population of the Ottoman empire; since, as already stated, every Moslem, if required, is obliged to join the army during time of war. The irregular cavalry is raised by the Znaims and Timariots, who hold feudal grants from the Porte on tenure of military service. The irregular infantry is assembled by the pashas and inferior officers in the provinces. Sixty years ago, the irregular cavalry constituted by far the most formidable and effective force belonging to Turkey; but the country whence it was derived having been wrested from the Porte by Catherine II., her enemies now use it with great effect against her.¹ The Khans of the Crimea were most useful tributaries of the Porte, and were at all times ready to take the field with from 40,000 to 50,000 horse of the very best description, considered as irregular troops. Brave, hardy, accustomed to support fatigue and privation, inured to riding from their infancy, and obedient to their leaders, the Crim Tartars formed the main strength of the Turkish armies; and, superior to the Timariots, who had become enervated by peaceful habits, were prepared for all kinds of service, nay even to encounter the best regular cavalry that could be brought against them. The loss of the Crimea, therefore, and of the enterprising troops it supplied, inflicted a severe, if not an irreparable, injury on the military resources of Turkey. The irregular cavalry is now principally drawn from the Asiatic provinces; but as the Mahommedan population has much decreased, this force is consequently less numerous than formerly. The irregular infantry, called Seimens, is furnished by the pashas, ayans, mous-selims, and voivodes; and, during the last war, some regiments so raised received pay from the Porte. The men were drawn from Rumelia and Asia; and it is not a little remarkable, that of those who distinguished themselves most in the field, the majority had belonged to the proscribed corps of janissaries, many of whom are still to be met with in all parts of the empire, notwithstanding the severe measures adopted for their extermination. The spirit of janissarism, indeed, is still latent in a large portion of the population. The sultan has scotched the snake, not killed it; and the utmost vigilance will be necessary on his part to prevent its resuscitation.

The military establishments of Turkey have yet, in a great measure, to be created; but the sultan is indefatigable in urging on improvement to the utmost extent of his crippled means. The only founderies for casting cannon are in Constantinople. They are three in number: one of two furnaces, attached to the military arsenal at Tophana; another, also of two furnaces, near the naval arsenal; and a third of one furnace at Hassquiou, the bombardier barracks. In one of these establishments sufficient metal can be melted to cast from five to seven guns at a time; but in all, the tools are of the coarsest description, and every thing is effected by manual labour, without the aid of machinery. The workmen are Turks and Armenians. The

Army. military arsenal at Tophana contains a large stock of artillery of various calibres, and some of extraordinary length.² The field-pieces are in tolerable order, but the guns have neither sights nor scales. A manufactory of muskets has existed for some years; but although as many as 120 can be made daily, the supply is found insufficient, and the troops are mostly armed with French muskets purchased at Marseilles. There are eight handsome barracks in and near Constantinople, viz. Daoud Pasha, Ramah Chiffic, the Seraskiers, Tophana, Scutari, Hassquiou, and the two Pera barracks, which have been erected either by Selim or Mahmoud, and are said to be capable of containing 72,000 men, although this is most probably an exaggeration. They are by far the most splendid edifices in Constantinople, and are considered equal to any structures of the kind in Europe. Schools or colleges of medicine, of the marine, of music, and of military instruction, have been recently established at Constantinople. The medical school contains about 100 students, and the number will probably be soon increased, as each regiment is to have both a physician and surgeon attached to it.³ Between three and four hundred young men are instructed at the military school, which is under the superintendence of the chief bombardier, in mathematics and the principles of fortification and gunnery; and some few French works upon military subjects have been translated into Turkish for the benefit of the students. Sultan Mahmoud has also established a kind of commissariat department, under the control of the Asker Nazir, or superintendent of the troops; but the establishment is yet in its infancy, and the arrangements are very imperfect. Greater progress has, however, been made in reforming the pay department, in which enormous abuses formerly prevailed; the troops and the sultan having been alike plundered by the knaves intrusted with this important branch of the public service. But since the management of the finance, commissariat, and general organization of the army has been vested in the Asker Nazir, conjointly with the seraskier and other high official persons, matters have been placed on a much better footing, and the soldiers have now little to complain of. The new military code has been modelled upon that issued by Sultan Suleiman, when he reformed the corps of janissaries, and restored their ancient discipline; and although it is still in many respects imperfect and defective, it seems, upon the whole, calculated to ameliorate the moral condition of the Ottoman soldier.

The reforms effected by Sultan Mahmoud in the military Greek organization of the Turks rendered it expedient for the army. Greeks to attempt to form regular corps, in order to keep on a level with their enemy in point of discipline and tactics. Accordingly, on the 27th February 1827, the president ordered a military force to be organized in regiments (*chiliarchies*) of two battalions (*pentacosarchies*), divided into five companies (*hecatoncharchies*) each; a regiment to con-

¹ During the last campaign the Turks had generally bad information, frequently none at all, respecting the movements of the Russians; whilst clouds of Cossacks scoured the country in every direction, cut off the Ottoman *éclaireurs*, explored all the routes and even bye-paths, and conveyed to head-quarters prompt intelligence of the slightest movement on the part of the enemy. It was this entire command of the communications which gave Diebitsch so great a superiority during the latter part of the campaign, and enabled him to surprise the vizier at Kiulewtscha, to mask the celebrated march by which he turned the barrier of the Hæmus, and to acquire for himself the well-merited distinction of Zabalkansky, or Passer of the Balkan. The troops sent to intercept him in the mountain gorges arrived too late, and Zabalkansky was thus enabled, with a handful of troops, to dictate peace in the ancient capital of the empire.

² Near the seraglio are several enormous guns carrying stone balls like those fired at our fleet when passing the Dardanelles in 1808. But cannon of this description can only be discharged with effect when the object passes their line of fire, as they are not mounted upon carriages, but built in a wall. Some of the guns at the Dardanelles carry balls twenty-six inches and a half in diameter.

³ There was nothing in Turkey which stood more in need of reform than the healing or rather the killing art. With all their predestinarian prejudices, the Osmanlees place unbounded faith in the skill and knowledge of physicians; and although they have been at all times ready to acknowledge the superiority of Europeans in the science of medicine, they have nevertheless for the most part been obliged to intrust the welfare of their bodies to empirical adventurers, whose knowledge had been acquired much in the same manner as that of the learned hakim Yacoub, so admirably described in "Anastasiou." Mahmoud's medical school, if it prosper, may in time have the effect of putting down those pernicious quacks.

Army. sist of a colonel (*chiliarch*), two chefs de bataillon (*pentacosiarchs*), 10 captains (*hecatontarchs*), 20 lieutenants (*pentacontarchs*), 40 sub-lieutenants (*eikosi-pentarchs*), 80 serjeants (*dodecarchs*), 160 corporals (*pentarchs*), and 800 soldiers; in all 1122 men. Another decree of the 17th October ordains the formation of a battalion of artillery of six companies, with a suitable cortège of officers; and embodies in it a sort of provisional code of military law. But little or no progress has as yet been made in the organization of a standing force; for the battle of Navarin and the war between Russia and Turkey removed the immediate stimulus of fear, which alone can make the Greeks carry through any thing; whilst the favourable turn which affairs have since taken, and the certain establishment of Greek independence, have rendered the measure in some degree unnecessary. We may add, that the decrees are drawn up in a very crude manner, and make no mention whatsoever of the number of chiliarchies or regiments which it was intended to raise.¹

American
armies.

The American armies require only a very cursory notice. That of the United States, exclusive of militia, does not amount to 10,000 men. It consists of seven regiments of infantry, four of artillery, some engineers, and a sort of general staff; and it is formed into three divisions, each under the command of a general officer. That called the eastern, under the orders of major-general Gaines, is composed of 53 companies, consisting of 233 officers, and 2662 non-commissioned officers and privates. The western division, commanded by Brigadier-General Atkinson, is also composed of 53 companies, amounting in all to 2463 men, including 178 officers. The third division, which has no relative territorial denomination, consists solely of recruits enlisted for the regular service in different parts of the union, and does not exceed 2500 men. The republicans of the west have a great aversion to a standing army, and only maintain a sort of skeleton, to be filled up, in case of need, from the militia force. The troops of the United States excel in bush-fighting; but they have neither organization nor discipline, and on any other soil than their own would be any thing but formidable.²—The Mexican army is considerable. A few years ago it consisted of 3 brigades of artillery, 12 battalions of infantry, 13 regiments of cavalry, 31 garrison companies, and 12 fixed companies of infantry and cavalry; making a total of 22,750 men: besides a militia of 42,017 men, of whom 21,577 were in active service. At the period referred to, therefore, the whole armed force of Mexico amounted to 64,697 men, of whom 44,327 were then in active service. Menaced with invasion by the mother country, and torn by contending factions, this new state cannot at present have fewer men under arms than at the time when the returns were made from which this brief notice has been drawn up.³—The black army of Hayti consists of the president's guard, with the infantry and artillery of the line. The guard, which ranks at the head of the army, consists of two regiments of infantry, one grenadiers and the other chasseurs, and three regiments of cavalry, one of carabineers, one of grenadiers, and one of chasseurs. There are 33 regiments of infantry of two battalions each, and every battalion has six companies, viz. one of grenadiers 80 strong, one of chasseurs 50, and four of fusiliers 44 men each. Attached to this infantry, and distinct from the guard, are

two regiments of dragoons of two squadrons, divided into two companies of 70 men each. The artillery consists of five regiments of two battalions, divided into nine companies of 50 men each, including officers. There is also an engineer corps, with 26 companies of 50 men each of artificers and pioneers. The whole of the Haytian force, therefore, including the staff and the president's guard, amounts to about 26,000 or 27,000 men.⁴—We are not in possession of any accurate details respecting the composition and force of the various South American armies. The Brazilian is estimated at from 35,000 to 40,000 men, including militia; the Colombian or Venezuelan at from 15,000 to 20,000; the Peruvian at 20,000; and the Chilian at from 10,000 to 12,000 men of all arms. But these numbers are in a great measure conjectural. The military force of the Argentine republic is probably not greater than that of Chili or Venezuela; while that of Paraguay amounts to about 5000 regulars and 20,000 militia.⁵

From time immemorial the inhabitants of the British Islands have been distinguished for a determined bravery, united with a degree of physical power, which belongs to the people of no other nation; and hence, as soldiers, they have never yet, when properly commanded, found their match in the field of battle. "L'Angleterre," says Count Turpin, in his commentaries on Montecuculi's *Mémoires*, "est elle peut-être la nation où la bravoure se soutient depuis le plus long temps." "Our nation," observes Dr Johnson, "may boast, beyond any other people in the world, of a kind of epidemic bravery, diffused equally through all its ranks; we can show a peasantry of heroes, and fill our armies with clowns whose courage may vie with that of the general." The valour of a Briton is innate. It is a national instinct, co-existent with and inseparable from the man himself, and requiring no artificial excitement to bring it into action; and it is as powerful at the present moment as it was in the chivalrous days of Cressy, Poitiers, and Agincourt. Hence, although the fortune of our arms may have varied, the character of the soldier has always remained the same; and at Waterloo as at Blenheim, and Ramilies, and Malplaquet, he established his superiority in all those high military qualities which render a nation invincible. But, from various causes, the reputation of the British army, which the campaigns of Marlborough had raised to the highest pitch, and which the various actions of the Seven Years War had gloriously sustained, began subsequently to decline; while the disastrous results of American revolutionary war created an opinion, which succeeding events appeared to confirm, of its total unfitness for prosecuting a lengthened series of operations, or contending with any prospect of success against the armies of other nations, particularly those of the Continent. It was conceived to be little better than a body of marines, well qualified to co-operate with the navy in partial expeditions, or in making descents on the sea-coasts of any country with which Great Britain happened to be at war, but incapable of maintaining itself in the field, or of engaging in regular campaigns; and, to say the truth, there were not wanting plausible reasons which might be alleged in support of such an opinion. For, as if they had been determined, not merely to countenance this impression, but really to render the army as inefficient and as utterly destitute of consistence and energy

as it was generally believed to be, the British ministry persisted for a series of years in wasting its strength in paltry expeditions, or in effecting partial descents upon this or that country, instead of combining one great effort calculated to influence the general result of the contest. Yet, in 1795, the regular army, including the force under the Duke of York in North Holland, exhibited a total of 119,000 men, besides about 42,000 employed in the colonies, in Corsica, in Gibraltar, and in Portugal; a force which, directed with skill and judgment, might have saved the country from many humiliations, prevented an enormous accumulation of debt, and accelerated the termination of a sanguinary and ruinous contest, from the effects of which the nation is still suffering. The campaign of Egypt, in 1801, showed, it is true, some small degree of energy, and, above all, afforded the army an opportunity of proving its undiminished excellence. But, unfortunately, on the renewal of the war in 1803, the old system was resorted to, and all the prejudices which had previously existed against the army were revived with tenfold force;—prejudices which outlasted the first successes of the Peninsular campaigns, and which were only at length overcome by an unexampled series of victories, obtained over the ablest generals and the best troops of which France could boast.

"The French army," says Colonel Napier, "was undoubtedly very formidable from numbers, discipline, skill, and bravery; but, contrary to the general opinion, the British army was inferior to it in none of these points save the first, and in discipline it was superior, because a national army will always bear a sterner code than a mixed force will suffer. With the latter the military, not the moral crimes, can be punished; men will submit to death for a breach of great regulations which they know by experience to be useful, but the constant restraints of petty though unwholesome rules they will escape from by desertion, or resist by mutiny, when the ties of custom and country are removed; for the disgrace of bad conduct attaches not to them, but to the nation under whose colours they serve. Great, indeed, is that genius that can keep men of different nations firm to their colours, and preserve a rigid discipline at the same time. Napoleon's military system was, from this cause, inferior to the British, which, if it be purely administered, combines the solidity of the Germans with the rapidity of the French, excluding the mechanical dulness of the one, and the dangerous vivacity of the other; yet, before the campaign in the Peninsula had proved its excellence in every branch of war, the English army was absurdly underrated in foreign countries, and absolutely despised in its own. It was reasonable to suppose that it did not possess that facility of moving in large bodies which long practice had given to the French; but the individual soldier was (and is still) most falsely stigmatised as deficient in intelligence and activity, the officers ridiculed, and the idea that a British could cope with a French army, even for a single campaign, considered chimerical. The English are a people very subject to receive and to cherish false impressions. Proud of their credulity, as if it were a virtue, the majority will adopt any fallacy, and cling to it with a tenacity proportioned to its grossness. Thus an ignorant contempt for the British soldiery had

been long entertained before the ill success of the expeditions in 1794 and 1799 appeared to justify the general prejudice. The true cause of those failures was not traced, and the excellent discipline afterwards introduced and perfected by the Duke of York was despised. England, both at home and abroad, was, in 1808, scorned as a military power, when she possessed, without a frontier to swallow up large armies in expensive fortresses, at least two hundred thousand¹ of the best equipped and best disciplined soldiers in the universe, together with an immense recruiting establishment, and, through the medium of the militia, the power of drawing upon the population without limit. It is true, that of this number many were necessarily employed in the defence of the colonies; but enough remained to compose a disposable force greater than that with which Napoleon won the battle of Austerlitz, and double that with which he conquered Italy. In all the materials of war, the superior ingenuity and skill of the English mechanics were visible; and that intellectual power that distinguishes Great Britain amongst the nations, in science, arts, and literature, was not wanting to her generals in the hour of danger."²

It is almost needless to add how conspicuously this brave and unequalled army disproved the calumnious prognostications of its contemners and revilers; how gloriously it established, in seven campaigns and more than twenty pitched battles, its superiority over the veterans of France, crowned with the laurels of a hundred victories, and accounted invincible till called to contend with the men of our soil. Let us now direct our attention to its composition and organization.

By the constitution of this country the king is the supreme head and captain-general of the army, which can receive no orders except such as emanate from him, and is bound to obey all his orders, unless at variance with the fundamental laws of the land; in which case submission to his authority would be declared rebellion against the constitution of the state, and the nation at large. To him belongs the power of declaring war and concluding peace, of granting subsidies to his allies and indemnities to his enemies: but no treaty is valid or binding unless it be signed by a responsible minister; and without the authority of parliament he cannot touch a sixpence of his subjects' money for this or any other purpose. Further, it is expressly declared in the bill of rights, and annually repeated in the preamble to the mutiny-act, which forms the martial law of the British army, "that the raising or keeping a standing army in time of peace, unless it be with the consent of parliament, is *against law*;" in other words, no military force can be raised or maintained in this country, except with the consent of the three estates composing the legislature, by which, in their collective capacity, the sovereign power of the state is exercised. But in regard to the existing army, all measures and all acts deemed necessary for its regulation, direction, and employment, are decided upon by the king in council; and it is the duty of the commander-in-chief of the forces for the time being to direct the execution of such measures or acts, in all those operations which are executed within the united kingdom, as well as to superintend the organization, instruction, and discipline of the troops belonging to the different branches of the service.

¹ At the period in question the British army consisted of 30,000 cavalry, 6000 foot-guards, 170,000 infantry of the line, and 14,000 artillery; in all 220,000 men. Of these between 50,000 and 60,000 were employed in the colonies and in India; but the remainder were disposable, because from 80,000 to 100,000 militia, differing from the regular troops in nothing but the name, were sufficient for the home duties. If to this force we add 30,000 marines, the military power of Great Britain, at the time referred to, must have exceeded 400,000 men, exclusive of local militia and volunteers.

² *History of the War in the Peninsula and in the South of France, from the year 1807 to the year 1814.* By W. F. P. Napier, C. B. Lieutenant-Colonel, H. P., 43d regiment, vol. i. p. 10 and 11.

Army. The secretary at war is, by the terms of his commission or appointment, bound to give effect to the orders of the commander-in-chief, issued with the approbation and consent of the sovereign; excepting in as far as these shall appear to be contrary to the rules of the service, or to make any alteration in the expenditure of the army: in which cases it is his duty to make reference to the lords of the treasury, and to act in strict conformity to their instructions. This minister, in fact, who is not a member of the cabinet, is specially charged with the administration of the war department in all its branches. He is the organ of communication between government and the army on the one hand, and between the army and the government on the other; and he acts as a check upon the commander-in-chief, while he is in his turn restrained by his responsibility to parliament, to the country, and to the laws.

The departments exclusively military are those of the adjutant-general, the quarter-master general, the barrack-master-general, the commissary-general, the paymaster-general, and the board of ordnance.

The adjutant-general's department consists of the adjutant-general himself, the deputy-adjutant-general, the assistant-adjutant-general, and the deputy-assistant-adjutant-general, with ten or eleven clerks, three messengers, and a keeper. The adjutant-general belongs to the personal staff of the king, and accompanies his majesty and the commander-in-chief in all their reviews and military inspections. He is named directly by the king, on the recommendation of the commander-in-chief, and has the rank of lieutenant-general, though for the most part only a major-general. The deputy-adjutant-general is also appointed by his majesty; but the secondary offices of the department are filled by persons nominated by the adjutant-general himself. This officer may be considered as the director of the *personnel* of the British army. Every thing relating to the effective or non-effective state of the troops; to formation, instruction, and discipline; to the direction and inspection of the clothing and accoutrements of the army; to recruitment, leaves of absence, or bounties to soldiers; to the employment of officers of the staff; and to ordinary or extraordinary and official returns relative to these different matters, whether required by his majesty, by the ministry, by the secretary at war, or by parliament; falls within the province of the department over which the adjutant-general presides. He is the regular channel through which commanders of corps communicate with the commander-in-chief; and all orders, special instructions, and general regulations issued by the commander-in-chief, relative to the organization, discipline, or instruction of the army, are prepared, addressed to the commanders of corps, and published by the adjutant-general, conformably to the direction of the commander-in-chief of the forces, acting in the name and on behalf of his majesty. The troops stationed in Scotland, however, instead of communicating directly with the adjutant-general's office in London, address themselves to the deputy-adjutant-general who resides at Edinburgh; and Ireland has an adjutant-general of its own. It is also the duty of the adjutant-general to prepare, weekly, for the commander-in-chief and the king, returns of the troops stationed in Great Britain and Ireland; and, monthly, for the commander-in-chief, the ministers, and the king, a general statement of all the forces both at home and abroad.¹

The quarter-master-general holds the same rank, and is appointed in the same manner, as the adjutant-general. His principal duties are to prescribe routes and marches,

to regulate the embarkation and disembarkation of troops, to provide quarters for them, to mark out ground proper for encampment, to execute military surveys, and to prepare plans and arrange dispositions for the defence of a territory, whether such defence is to be operated by the troops alone or by means of field-works. Every British army on service has a quarter-master-general, with deputies and assistants, who perform functions altogether analogous to those which are discharged in the department of quarter-master-general of the British forces; and it is admitted on all hands that, during the Peninsular campaigns, this branch of service was, under the very able direction of Sir George Murray, carried to a high degree of perfection. Whenever the army, established for the time in any position whatever, had to move in advance and in a given direction, all the officers of the quarter-master-general's staff, charged with the reconnaissances, immediately set out and spread themselves over the ground, each individual taking the direction indicated to him, and pushing his reconnaissance to the extent of a day's march of the army. About five in the afternoon these officers returned to head-quarters; and by combining their different partial sketches, a general plan was prepared, according to which the quarter-master-general and the commander-in-chief traced the routes to be followed, and the positions to be taken up, by the troops who were to march on the morrow. This was the duty of every day while the army was in motion; and no better evidence can be produced of the ability with which it was performed, than the circumstance that, during the whole of the Peninsular campaigns, the army never once took up a position in which it could be assailed by the enemy, however superior in numbers, with the remotest chance of success. Attached to the office of quarter-master-general of the forces is a board of topography, with a dépôt of maps, plans, and military memoirs, and a library containing the best military works that have been published in different countries.²

The barrack-master-general's department is a numerous one, consisting of ninety functionaries in London, and eight in Edinburgh, exclusive of barrack-masters, store-keepers, hospital-store-keepers, barrack-sergeants, and clerks. His principal duty is to provide barracks, permanent as well as temporary, for the reception of the troops; to superintend their construction or repair; and, generally, to take care that the troops are properly accommodated, both as to room and otherwise. Subordinate to him, of course, are all the local barrack-masters, whose duty it is to furnish bedding and other necessities for the troops in their respective barracks. Ever since 1805, Great Britain has had 84 barracks built of stones or bricks, 12 constructed of timber, 75 temporary barracks, and 48 hired for rent, in all 212; which, it is calculated, are sufficient for affording accommodation to 100,000 infantry and 15,000 cavalry.

The commissariat department, when complete, consists of a commissary-general, a deputy-commissary-general, an assistant-commissary-general, and a deputy-assistant-commissary-general, with upwards of two hundred subordinate functionaries. The head of the department is the commissary-general, who resides in London, and directs the whole of this branch of the service, whether at home or abroad. Subordinate to the treasury in as far as regards financial matters, he is at the same time under the control and direction of the war-office in reference to military operations. His duties, which have been greatly increased since the report of the special committee of finance in the year 1797, consist in supplying provisions, forage, and camp as well as barrack equipage, to the troops;

¹ Dupin, *Force Militaire de la Grande Bretagne*, l. ii. p. 54.

² *Ibid.* l. ii. p. 59.

in providing the materials of the medical department of the service; and, generally, in directing and superintending all those furnishings which usually enter into the army extraordinaries of the year, of which he prepares a monthly account for the treasury, and an annual return to be laid before parliament. Three months after the close of every year, he also lays before the auditors of public accounts a financial statement of the receipts and disbursements of the preceding year; before the comptrollers of the army, a general view of the receipt, deliverance, and consumption of supplies furnished by his department; and before the lords of the treasury, a detailed account of the various items of expenditure, of the pay and half-pay of persons attached to the commissariat, as well as of the expense of field-works and signals. All the furnishings of provisions, forage, &c. made to the troops stationed in Great Britain are supplied by army contractors; but, for other articles, the commissariat finds it more advantageous to pass a contract at the moment of need, and for the quantity required, than to enter into any permanent engagement beforehand for the supply of particular articles. The accounts of the contractors, after being compared with the regimental receipts, as certified by the commanders of corps, are then transmitted to the war-office to be again compared, by the superintendent of army accounts, with the effective force and distribution of the different corps, as well as with the regimental returns; and the concordance of these different verifications serves in the first instance as a guarantee to the ministry. The commissary-general has neither the custody nor the delivery of any supplies or materials whatever; nor does he keep any account of disbursements made out of Great Britain.¹ Every army in active service has its own commissariat, under the orders of a commissary-general, who is responsible, in the first instance, to the general-in-chief, for the regular supply of the troops under his command. In Portugal and in Spain, the provisioning of the army was effected by all the means to which recourse could be had in countries so poor and exhausted; but the greater part of the necessary supplies was obtained by purchases effected by commissaries stationed at different places or attached to brigades, and paid from funds supplied by the commissary-general of the army, consisting partly in cash, and partly in bills or debentures on the English government. Immense abuses appeared to have prevailed in the commissariat department during the early part of the peninsular campaigns. This is evident from the repeated orders of the day issued by the Duke of Wellington against malversations on the part of subordinates in this department; and not less so from the fact that, notwithstanding all the care and vigilance exercised by his Grace, many of these functionaries managed to realise fortunes.²

The paymaster-general is the head of the army pay-office, whence the issues for the payment of every description of military service are made. This office consists of the paymaster-general himself, two deputies, an accountant-general, a cashier, book-keepers, clerks, and other subordinates; and there are several deputy-paymasters abroad

subordinate to the general department at home. The paymaster-general has no active control over the expenditure of the public money. His duty is merely to make payments ministerially and without discretion, in pursuance of the warrants directed to him by the secretary at war, the treasury, or both, as the case may be; or in honour of the drafts of the deputy-paymasters abroad, for the ordinary services of the army. The pay-office must therefore be looked upon as an office of account merely, and as affecting the public expenditure only in as far as it performs the duties of an office of accounts with regularity and expedition. The materials and documents, which compose a considerable part of the account of the paymaster-general, originate with persons over whose conduct he exercises no manner of control. Indeed there is a regular succession in preparing them, from the regimental paymaster to the agent, and from the agent to the secretary at war, who finally delivers them at the pay-office. Different classes of accounts and documents are delivered in at certain periods prescribed by the pay-office act. But large balances of the public money are not now, as formerly, allowed to remain in the hands of the paymaster-general, or at his credit in the bank; nor can he derive any profit from the custody of the public money, the balances being confined within the narrowest possible limits. The establishment of a regiment, with the king's regulations and warrants, is in fact the instrument which regulates the pay of the army, and is consequently the basis of all the documents which enter or go out of the pay-office under that head of the service.³ Other details are foreign to the immediate object of this sketch, which is merely to give a brief outline of the constitution and functions of those departments immediately connected with the army.

The ordnance department, which comprehends the artillery and engineers, is administered and commanded by a master-general, assisted by a council or board, composed of the lieutenant-general of the ordnance,⁴ who in the absence of the master-general directs the military part; of the inspector-general, who, with his agents, has the control of the munitions and stores, as well as of the accounts; of the commissary, who has the direction of the accounts both in money and materials, and who prepares every month for the treasury, and every year for parliament, the ordnance estimates; of the principal storekeeper, who is responsible for the existence and conservation of the whole *matériel*; and of the clerk of deliveries, who has the superintendence of whatever goes out of the magazines. The written orders of the master-general are of course executory in all the branches of this department; but he commonly intrusts to the board the administration of the *matériel* and of the expenditure. In case of absence or vacancy, and when the master-general does not of himself exercise any part of his authority, the board in like manner officiates in his stead. The ordnance has a special paymaster or treasurer, who advances the funds necessary for the department, on orders or drafts, signed by at least three members of the council. Almost all the officers of the board are at the same time members of the House of Commons.

¹ Dupin, *Force Milit. de la Grande Bretagne*, l. iv. c. iii. p. 149. James's *Military Dictionary*, voce Commissary-General.

² La trésorerie (says M. Dupin) faisait toutes les avances de fonds à l'armée d'Espagne sur les estimations anticipées du commissaire-général, vues et approuvées par le général en chef, et par lui transmises (comme *duplicatum*) au secrétaire d'état de la guerre et des colonies. Ensuite le commissariat payait moitié en espèce, moitié en obligations du gouvernement Anglais." (*Voyages dans la Grande Bretagne*, prém. part. *Force Militaire*, p. 153.) From the ignorance of the Spaniards, however, or rather perhaps from their experience of the faithlessness of their own government, these "obligations" or bills became speedily depreciated to the extent of 26 or 30 per cent., and were purchased from the peasantry and farmers at this discount by the commissaries, who, of course, realized an enormous profit on these transactions. At one period of the Peninsular war the depreciation exceeded 50 per cent.; but the avidity of the commissaries to purchase the debentures increased the confidence of the people in their validity, and thus reduced the depreciation to the amount above stated.

³ James's *Military Dictionary*, voce Pay-office.

⁴ This office it is now proposed to abolish.

Army.

The sums voted for the support of this department proceed upon estimates of the ordinary and extraordinary service, and of services unprovided for. The ordinary service comprehends the provision for the ordinary establishment, civil and military, for the year ensuing; the extraordinary includes every service known beforehand, of a temporary and contingent nature, during the currency of the year; and the services unprovided for consist of services which have either been actually paid for in the course of the past year, or which are supposed to have been paid, but which were not foreseen when the estimates of the preceding year were prepared. Among these unforeseen expenses are included various exceedings which may have occurred in the individual services voted in the ordnance estimates of the previous year; to which are commonly added such sums as may be considered necessary to make up the deficiency of the sum allotted to the ordnance for the use of the naval service. So much for the military departments.¹ Let us now attend to the composition of the army itself.

The British army consists at present of 8818 cavalry and 95,786 infantry; but of this force 2804 cavalry and 17,312 infantry are employed in the East India Company's territories; leaving an available force provided for in the estimates of the year 1830 of 6014 cavalry and 78,474 infantry, or 89,284 men of all arms, including officers. This force is divided into cavalry, infantry, artillery, engineers, and some corps immediately connected with the two latter branches of the service, as the royal artificers, the artillery-drivers, and the royal waggon train.²

The *cavalry* on home service consists of the first and second regiments of life-guards, and the royal regiment of horse-guards (blue), each of 344 rank and file and 274 horses, with nineteen other regiments of dragoon-guards and dragoons; namely, seven of dragoon-guards, three of dragoons, and nine of light-dragoons, including lancers and hussars, amounting to 5897 rank and file, with 4892 horses; or, including the regiments of life-guards, 6919 rank and file, and 5714 horses. In this enumeration, however, the cavalry serving in India, the waggon-train, and the Cape corps of mounted riflemen, are not included. The first regiment of dragoon-guards consists at present of 407 rank and file, and 307 horses; but the remaining regiments of the cavalry of the line have only 305 rank and file and 253 horses each. The officers and non-commissioned officers of a regiment of life-guards, on its present establishment, amount to 89; of a regiment of the cavalry of the line, to between 60 and 70.³ Thus, supposing the latter to consist of 368 privates, divided into 8 companies or squadrons, such a regiment would have 1 colonel, 2 lieutenant-colonels, 2 majors, 8 captains, 8 lieutenants, 8 cornets, 1 paymaster, 1 adjutant, 1 quarter-master, 1 surgeon, 1 assistant-surgeon, and 1 veterinary-surgeon, or 35 officers in all; besides 28 sergeants and 8 trumpeters; making a total of 71 officers and non-commissioned officers, and raising the entire strength of the regiment to 439 men. And the same relative proportion obtains, whatever be the footing in point of effective force, on which the regiment is placed.

Since the peace of 1815, various changes have been made in the arms and equipments of our cavalry. In the first place, armour was given to the life-guards, immediately after they had proved its total inefficiency in the field of battle, and torn the laurels of Waterloo from the re-

doubted cuirassiers of France. That armour must prove a decided impediment to the efficiency of a dragoon on service, is what no one can for a moment doubt. Its enormous weight,⁴ the constant cleaning which it requires, the pain which its inflexibility must occasion under fatigue, and the obstacles it opposes to the free and full action of the muscular powers of the human body, greatly detract from its advantages. These, moreover, have been over-rated; and we are much mistaken if it will not one day be shown that the life-guards, encumbered with the cuirasses, are immeasurably less formidable than they were when their natural strength, weight, and activity, had full freedom of action allowed them. In the next place, four of our regiments of light horse have been converted into lancers. We agree in opinion with Montecuculi that the lance "est la reine des armes pour la cavalerie;" and we also think, with Major Beamish, that lancers should constitute the standard cavalry of England. But we do not the less object to the particular kind of lance introduced into our service, and the description of cavalry to whom it has been assigned. No nation possesses such materials as Britain for the formation of redoubtable lancers; no nation has the command of such means of bringing them to perfection: and if solid squares of infantry are ever to be penetrated by cavalry, it must be performed by cavalry armed with the lance. But this will never be achieved by such a weapon as that at present in use. It must be effected by a lance of sufficient length to overcome the infantry bayonet, which, thus opposed, would no longer be formidable; and this lance must be put into the hands of our heavy cavalry, particularly the household troops, which, thus armed, would be able to contend on equal terms with the best infantry in the world, and would unquestionably be capable of penetrating its closest formation.

The British *infantry* on home service is composed of 3 regiments of guards, viz. the 1st or grenadier regiment, the Coldstream regiment, and the 3d regiment, amounting together to 5104 rank and file; of 79 regiments of the line, consisting of 1 battalion each, 740 strong; of one regiment (the 60th foot) and the rifle brigade, two battalions each; of 2 West India regiments, the royal waggon train, 2 companies of the royal staff corps, 3 Newfoundland and 3 royal veteran companies, the African corps, the Ceylon regiment, and the Cape corps of mounted riflemen; making a total of 66,240 men, exclusive of the guards. The regiments of infantry of the line have only one battalion as a constant nucleus. When additional battalions are raised, they are employed separately, and commanded each by a lieutenant-colonel. With regard to the colonelcy of a regiment, it is in a great measure a sinecure. The ordinary staff of a battalion of 800 men, rank and file, consists of 1 lieutenant-colonel, 2 majors, 10 captains, 12 lieutenants, 8 ensigns, 1 paymaster, 1 adjutant, 1 quarter-master, and 1 surgeon with 2 assistants; in all 39 officers. The petty staff is composed of a sergeant-major, a quarter-master sergeant, a paymaster sergeant, an arm sergeant, a school-master sergeant, 10 colour sergeants, 30 sergeants, a drum-major, and 21 drummers; in all 106 men. Hence the total strength of such a battalion would consist of 39 officers, 106 non-commissioned officers, 40 corporals, and 760 soldiers, or 906 men in all.⁵

The force at present serving in India consists of 4 regiments of light dragoons, each 701 strong, or 2804 in all;

¹ Dupin, l. v. c. 1, p. 175.

² Estimates of Army Services for the year 1830 (Parliamentary paper).

⁴ The largest sized cuirass worn by the life-guards weighs 15 pounds; the smallest 12 pounds 6 ounces. A life-guardsman, in marching order, weighs upwards of 25 stone, supposing the man personally to weigh 13 stone! Besides, these cuirasses are as ugly as they are weighty, and give to the really fine men who are compelled to wear them an appearance of being hump-backed.

⁵ Army Estimates for 1830.

³ Army Estimates for 1830.

and 21 battalions of infantry, each 740 strong, or, including supernumeraries and others, 17,312 in all.

The royal artillery forms only one corps, which is absurdly denominated a regiment, since, in time of war, it is increased to more than 24,000 men. The master-general of the ordnance has the title and powers of colonel of the regiment of artillery; the lieutenant-general of the ordnance is lieutenant-colonel; and a general officer, with the title of deputy-adjutant-general, performs the functions of head of the artillery-staff, but is in no way dependent upon the adjutant-general of the British forces. The board of the deputy-adjutant-general of artillery is at Woolwich, which may be considered the head-quarters of the ordnance. The royal artillery corps consists of the brigade of horse-artillery, and of the artillery serving on foot. The horse-artillery is subdivided into companies called troops, varying in number from six to ten. Of these two served in the Peninsula in 1808, five in 1813, and seven at Waterloo in 1815. It is under the orders of 2 colonels commanding, 2 colonels *en second*, 2 lieutenant-colonels, and 1 major; while each company or troop is commanded by a captain of the first rank, a captain of the second, and 3 lieutenants. The foot artillery is divided into battalions of ten companies each, under the orders of 2 colonels, first and second, 2 lieutenant-colonels, 1 major, 1 adjutant, 1 quarter-master, and a surgeon with 2 assistants in time of war, and 1 during peace. In the year 1792, there were 4 battalions of foot artillery of 820 men each, with one of invalids containing 483; making 3707 in all. In 1814, there were 16,157 artillery-men, forming 11 battalions of 1459 men each. In 1819 there were only 9 battalions of 8 companies and 638 men each, or 5742 in all; which is pretty nearly the actual strength of this arm. The rocket corps is attached to and forms part of the artillery; and the same thing holds of the royal artificers, the royal waggon train, and the artillery drivers.¹

In the war which preceded the peace of Amiens, and even in the early campaigns in Portugal, the *engineer* department was in a very ineffective condition; particularly from the want of the necessary means of transport, and partly also from a deficiency both in the number and quality of military artificers. In order to remedy these inconveniences, the Duke of Wellington, in 1814, caused a brigade of engineers, consisting of a company of sappers and miners, with horses, cars, and drivers, to be attached to each division of the army, and to be regularly trained and exercised in field duties, as well as in those which might be required of them in sieges. A captain and a certain number of subalterns were specially attached to each brigade, and were held responsible for the effective condition both of the men and the horses. Thus the remainder of the engineers, free from any embarrassments relative to the *matériel* and *personnel* of that department of the service, were enabled to give their undivided attention to important military operations, and to contribute, in a most essential manner, towards the success of the succeeding campaigns. Five companies of sappers and miners also served with the pontoon-train, which consisted of eighty pontoons, besides forges, waggons, &c. drawn by about 800 horses; the whole under the orders of a major of the brigade of engineers. Since the peace great attention has been paid both to the instruction and organization of this important branch of the service; which, in the event of another war, will be found on a very different footing, in point of efficiency, from that on which it stood during the greater

part of the Peninsular campaigns. Experience taught important lessons, which have been suitably and effectually improved.

The portion of the British army presently serving in India amounts, as we have already seen, to about 20,000 men. The European troops in the company's service consist of 8000 infantry and 4000 artillery; while the native regular troops are, according to the best information, composed of 10,000 cavalry, 130,000 infantry, and 8000 artillery; and the native irregular force, of 7000 cavalry and 17,000 infantry. Our Indian army, therefore, may be considered as amounting to 19,000 cavalry, 168,000 infantry, and 12,000 artillery, or, in all, about 200,000 men. The organization of the native army being, in all essential respects, the same as that of the British army, no particular description of it seems to be required under this head.²

The character of the British army has been earned in battle and attested by victory. Wherever it has been even tolerably led, it has conquered; nor is there any army in the world which has sustained so few serious reverses. The elements of which it is composed are such as, if fairly developed in action, must, on any thing like equal terms, insure victory: for not only are the soldiers more robust, and possessed of greater physical power (or, as it is technically called, *bottom*), than those of any other nation, but they are also distinguished by an unflinching, indomitable courage, which may be safely reckoned upon at all times and in all circumstances; which it is often difficult to restrain, but never necessary to excite; and which always rises to a pitch of sublime elevation at the prospect of the charge and the close combat. They are the only troops in the world who look with indifference on naked points, and who are constantly impelled by a powerful instinct to close with their enemy; who maintain the distant battle with unyielding steadfastness, yet rejoice when the moment arrives that is to rest the issue of the conflict on the bayonet's point, and a struggle hand to hand with the enemy. Hence their fire is close, steady, and destructive; their charge, where it can be given, irresistible. "Les troupes Anglaises," says General Jomini, "se distinguent par leur bonne discipline et leur sang-froid; le soldat s'y enrôle pour la vie [this is a mistake; soldiers may enlist for any period], ce qui est bien extraordinaire chez un peuple si jaloux de sa liberté, mais ce qui ne surprend pas moins, c'est qu'il est docile et soumis: ces qualités essentielles qui constituent une armée solide, sont peut-être préférables à une valeur brillante mais passagère. Les unes sont permanentes; l'autre, justifiant le proverbe Espagnol, dépend de tel jour et de telle circonstance. La résignation et la discipline unies au courage froid, ont des résultats invariables et sûrs; elles produisent l'ensemble sans lequel il n'est point de véritable force."³ M. Dupin, in that part of his able work in which he treats of the military force of Great Britain, delivers an opinion somewhat similar to that expressed by Jomini, though shaded by certain qualifications and abatements.

"Il faut de dire," says he, "après les Français, tels qu'ils ont été pendant vinq-quatre ans dans nos armées, les Anglais sont les militaires les plus actifs de tout l'Europe; ils le sont d'une manière qui leur est propre. Leur activité n'a pas les élans prodigieux dont nous avons tant fois offert de mémorables exemples; mais elle n'a jamais d'intermittence, et se montre toujours la même. Cela lui fait produire, au bout d'un temps donné, une somme de résultats plus grande qu'on n'aurait pu le prévoir, d'après la vue d'une action

¹ Dupin, *Force Milit. de la Grande Bretagne*, l. v. c. 4, p. 196.

² Dupin; *Army Estimates for 1830*; and *Bulletin des Sciences Militaires*.

³ Jomini, *Guerres de la Révolution*, tom. ii. p. 252.

Army. isolée même la plus brillante. Le soldat Bréton a généralement moins d'esprit naturel et de pénétration que le soldat Français; mais l'immobilité de son imagination rend ses actions plus mesurées. Moins distrait par la vue des objets extérieurs, par les souvenirs du passé, par les espérances ou les terreurs de l'avenir, il est toujours tout entier au moment présent. Plus attentif au commandement actuel, il compense ainsi *l'infériorité de son intelligence*. Incapable de juger les grands mouvemens qui s'exécutent, et surtout ceux qui vont s'exécuter, pour ou contre lui, le danger futur ne se peint pas même à sa pensée. Il va donc à la mort *présente* sans s'inquiéter de la mort *à venir*. Voilà pourquoi le moral de l'armée Britannique est presque impossible à détruire par la mauvaise fortune."¹

In this passage there is some truth, mixed up with much nonsense and misrepresentation. The British soldier, it seems, is inferior to the French soldier in intelligence. And why? Because he does not concern himself about "grand movements executed and to be executed;" and because he is more attentive to command, and goes to *present* death without disturbing himself about *death to come*. These appear strange grounds upon which to rest the alleged superiority of the French or the inferiority of the British soldier in point of intelligence. That a native of this country, admitted on all hands to be at least one of the most intellectual on the face of the earth, should be at once metamorphosed by a red coat into a mere automaton or lump of living but impassible matter, would indeed be an extraordinary phenomenon; nor must it appear less singular that the French armies, with all their intellectual superiority, and all their attention to "grand movements," should have been constantly overthrown by our animated machines. But the plain fact is, that the assertion is wholly erroneous. The English soldier is inferior to no other that ever existed in point of intelligence; and even the late General Foy, whose book appears to have been written chiefly for the purpose of calumniating our army, makes admissions which show that such was his own real opinion, while maintaining a contrary one. This officer repeatedly says that the non-commissioned officers of the British army are superior in activity, intelligence, and zeal to those of the same rank in any other army, not excepting the French; and that this superiority was conspicuously evinced throughout the whole of the Peninsular campaigns. But these persons are taken almost indiscriminately from the ranks, and of course must represent the average amount of intelligence and activity diffused amongst the private soldiers; a circumstance which General Foy had not adverted to when he made the admission in question; for he was too good a Frenchman to allow British soldiers any merit which he could decently and with any show of probability deny them.

But the best answer to all his captious and querulous strictures is to be found in his own description of the conduct of the British regiments at Waterloo. "The cavalry which supported them," says he, "was cut to pieces [this is not true], the fire of their artillery completely silenced. The general and staff officers were galloping from one square to another, not knowing where to find shelter. Carriages, wounded men, parks of reserve, and auxiliary troops, were all flying in disorder towards Brussels. Death was before them, and in their ranks; disgrace in their rear. In this terrible situation, neither the bullets of the imperial

guard, discharged almost point-blank, nor the victorious cavalry of France, could make the least impression on the immovable British infantry. One might have been almost tempted to fancy that it had rooted itself in the ground, but for the majestic movement which its battalions commenced some minutes after sunset, at the moment when the approach of the Prussian army apprised Wellington that—thanks to numbers, thanks to the force of inert resistance, and as a reward for having contrived to draw up brave fellows in battle—he had just achieved the most decisive victory of our age."² The British army can desire no better panegyric than this, pronounced by a beaten enemy; and if the French shall continue to comfort themselves with the idea that the British soldier is deficient in intelligence, because he possesses that strength of mind which no danger can appal, and that tenacity which carries off the prey by sticking to it to the last, it would certainly be a pity to deprive them of any slender consolation which they may derive from cherishing such a delusion. But instead of adding any thing further of our own, we shall conclude by citing an authority which, on this as on all other military subjects, is universally admitted to be of the highest order.

"That the British infantry soldier," says Colonel Napier, "is more robust than the soldier of any other nation, can scarcely be doubted by those who, in 1815, observed his powerful frame, distinguished amidst the united armies of Europe; and, notwithstanding his habitual excess in drinking, he sustains fatigue, and wet, and the extremes of cold and heat, with incredible vigour. When completely disciplined, and three years are required to accomplish this, his port is lofty, and his movements free: the whole world cannot produce a nobler specimen of military bearing; nor is the mind unworthy of the outward man. He does not indeed possess that presumptuous vivacity which would lead him to dictate to his commanders, or even to censure real errors, although he may perceive them; but he is observant, and quick to comprehend his orders, full of resources under difficulties, calm and resolute in danger, and more than usually obedient and careful of his officers in moments of imminent peril.

"It has been asserted that his undeniable firmness in battle is the result of a phlegmatic constitution, uninspired by moral feeling. Never was a more stupid calumny uttered. Napoleon's troops fought in bright fields, where every helmet caught some beams of glory; but the British soldier conquered under the cold shade of aristocracy: no honours awaited his daring, no despatch gave his name to the applauses of his countrymen; his life of danger was uncheered by hope, his death unnoticed. Did his heart sink therefore? Did he not endure with surprising fortitude the sorest of ills, sustain the most terrible assaults in battle unmoved, and, with incredible energy, overthrow every opponent; at all times proving that, while no physical military qualification was wanting, the fount of honour was also full and fresh within him?

"The result of a hundred battles, and the united testimony of impartial writers, of different nations, have given the first place amongst the European infantry to the British; but, in a comparison between the troops of France and England, it would be unjust not to admit that the cavalry of the former stands higher in the estimation of the world."³

Arnall
Arnauld.

ARNALL, WILLIAM, a political writer, who was employed by Sir Robert Walpole to write the *Free Briton* in defence of his administration, for which, by the report of the secret committee, he is said to have received L.10,997. 6s. 8d. He died in 1741, at the age of 26.

ARNAUD BELGARD, a town of Turkey in Europe, in Albania. It is situated on the Chervesta, 40 miles N. E. of Vallona, in a fertile plain, covered with vines and olives. It is the seat of a Greek bishop, and contains 11,500 industrious inhabitants, who trade largely.

ARNAUD DE MEYRVEILH, or MEREUIL, a poet of Provence, who lived in the beginning of the 13th century. He wrote a book entitled *Las Recastenas de sa Contesse*, and a collection of poems and sonnets. Petrarch mentions him in his *Triumph of Love*. He died in the year 1220.

ARNAUD DE RONSIL, *George*, son of an eminent surgeon at Paris, and some time professor of surgery in the college of St Côme. On account of an accident that occurred while he was practising midwifery, he removed from Paris to London, where he acquired great repute by his operations, and his writings on surgical subjects. Before his time the treatment of *hernia* had been but imperfectly understood; and the surgeons of this country are indebted to the observations of Arnaud for many of those improvements which have since rendered their practice so successful in this branch of the art. The following is a list of his principal works:—1, *Traité des Hernies ou Descentes*, 2 vols. 12mo, Paris, 1749. 2, *Observations on Aneurysms*, London, 1750. 3, *Instructions on the Diseases of the Bladder and Urethra*, London, 1763. 4, *A Dissertation on Hermaphrodites*, London, 1750. These were afterwards collected and published, with additions, under the title of *Mémoires de Chirurgie, avec quelques Remarques sur l'Etat de la Médecine et de la Chirurgie en France et en Angleterre*, 2 vols. 4to, London, 1768. 5, *Remarks on the Use of the Extract of Lead of Goulard*, London, 1776. Arnaud died in 1774.

ARNAUD DE VILLA NOVA, a famous physician, who lived about the end of the 13th and beginning of the 14th century. He studied at Paris and Montpellier, and improved himself by visiting the schools of Italy and Spain. He was well acquainted with languages, particularly with the Greek, Hebrew, and Arabic. His desire after the acquisition of knowledge was ardent, but it carried him too far in his researches. He put unlimited faith in astrology, and published a prediction that the consummation of the world would take place in the middle of the 14th century. He practised physic at Paris for some time; but having advanced some new doctrines, he drew upon himself the resentment of the university; and his friends, fearing he might be arrested, persuaded him to retire from that city. Upon his leaving France he went to Sicily, where he was received by king Frederic of Arragon with the greatest marks of kindness and esteem. Some time afterwards this prince sent him to France to attend pope Clement in an illness; and he was shipwrecked on the coast of Genoa about the year 1313. His works, with a life prefixed, were printed at Lyons in 1520, in one volume folio, and at Basil in 1585, with the notes of Nicholas Tolerus.

ARNAULD, ANTONY, a very celebrated doctor of the Sorbonne, was born in 1612. He published in 1643 *A Treatise on Frequent Communion*, which highly displeased the Jesuits; and the disputes upon grace, which broke out about this time in the university of Paris, and in which he took a zealous part with the Jansenists, helped to increase the animosity between him and the Jesuits. But nothing raised so great a clamour against him as the two letters he wrote *On Absolution*; in the second of which the faculty

of divinity found two propositions which they condemned, and M. Arnauld was expelled the society. Upon this he retired; and during a retreat which lasted nearly twenty-five years, he composed that great variety of works which are still extant, on grammar, geometry, logic, metaphysics, and theology. In 1679 he withdrew from France, lived in obscurity in the Netherlands, and died in 1694. His heart, at his own request, was sent to be deposited in the Port Royal. Arnauld was a man of genius, remarkable for the strength of his memory and a command of his pen, which he possessed unimpaired to the last year of his life. Mr Bayle says, he had been told by persons who had been admitted into his familiar conversation, that he was a man very simple in his manners; and that unless any one proposed some question to him, or desired some information, he said nothing that was beyond common conversation, or that might make one take him for a man of great abilities; but when he set himself to give an answer to such as proposed a point of learning, he seemed as it were transformed into another man: he would then deliver a multitude of fine things with great perspicuity and learning. A complete collection of his works, extending to 45 vols. 4to, was published at Lausanne in 1777–83.

ARNAY-LE-DUC, a town of France, in the department of Cote d'Or, which carries on a pretty good trade. It is seated on the Auxois, in a valley near the river Aroux. Long. 4. 26. E. Lat. 47. 7. N.

ARNDT, JOHN, a famous Protestant divine of Germany, born at Ballenstadt, in the duchy of Anhalt, in the year 1555. He died in 1621. His *Treatise on True Christianity* has been translated into several languages.

ARNE, THOMAS AUGUSTINE, doctor of music, was born in King Street, Covent Garden, where his father was an upholsterer. He served three years with an attorney; but his strong propensity for music prevailed over the law, and he finally attached himself to the science, in which he soon became so eminent as to receive the degree of doctor from the University of Oxford in 1759. His compositions are numerous, he having adapted upwards of thirty musical pieces for the stage. They are characterized by a natural ease and elegance, a flow of melody, and a fullness and variety without affected or extraneous modulation. His most celebrated works are, *Artaxerxes*, which he paraphrased from Metastasio; the *Masque of Comus*; the *Opera of Operas*, a burletta; the *Guardian Outwitted*; and the *Rose*; some of which have taken a permanent hold of the stage. Dr Arne died March 5, 1778.

ARNHEM, one of the circles into which the province of Guelderland in the Netherlands is divided. It comprehends 14 cantons, and contains 74,451 inhabitants.

ARNHEM, the capital city of the province of Guelderland, in the circle of the same name, on the banks of the Rhine. It is well built, and its fortifications being planted with trees, form a pleasing promenade. It is a place of little trade, but of some importance as a frontier town. It contains 1490 houses, and 9500 inhabitants. Long. 5. 38. 23. E. Lat. 51. 59. 58. N.

ARNISÆUS, HENNINGUS, a philosopher and physician of great reputation about the beginning of the 17th century. He was born at Halberstadt in Germany, and was professor of physic in the university of Helmstadt. His political works are much esteemed. The most remarkable of them is his book *De Autoritate Principum in Populum semper Inviolabili*, printed at Frankfort in 1612. In this he maintains that the authority of princes ought not to be violated. He wrote also upon the same doctrine his three books, *De Jure Majestatis*, printed at the same place in 1610; and his *Reflectiones Politicæ*, printed at Frankfort in 1615. He went to Denmark by invitation, and was made counsellor and physician to the king. He travelled

Arnay-le-
Duc
||
Arnisæus.

Arnobius into France and England, and died in November 1635. Besides the pieces already mentioned, he wrote several philosophical, medicinal, and poetical treatises.

Arnoldus.

ARNOBIUS, professor of rhetoric at Sicca, in Numidia, towards the end of the third century. Owing to certain dreams which he had, he became desirous of embracing Christianity, and for this purpose applied to the bishops for admission into the church; but his former violent hostility to the faith led them to distrust him, and, before they would consent, they insisted on some proofs of his sincerity. In compliance with this demand, he wrote against the Gentiles, refuting the absurdities of their religion, and ridiculing their false gods. In this treatise he has employed all the flowers of rhetoric, and displayed great learning; but from an impatience to be admitted within the pale of Christianity, he is thought to have been in too great a hurry in composing his work, as there does not appear in it so complete an order and disposition as could be wished; and not having a perfect and exact knowledge of the Christian faith, he published some very dangerous errors. Mr Bayle remarks, that his notions about the origin of the soul, the cause of natural evil, and several other important points, are highly pernicious. St Jerome, in his epistle to Paulinus, is of opinion that his style is unequal and too diffuse, and that his book is written without any method; but Dr Cave thinks this judgment too severe, and that Arnobius wants neither elegance nor order in his composition. Vossius styles him *the Varro of the ecclesiastical writers*. Du Pin observes that his work is written in a manner worthy of a professor of rhetoric: the turn of his sentiments is very oratorical; but his style is a little African, his expressions being harsh and inelegant. We have several editions of this work of Arnobius against the Gentiles; one published at Rome in 1542, at Basil in 1546 and 1560, at Paris in 1570, at Antwerp in 1582, and one at Hamburg in 1610, with notes by Geverard Elmenhorst, besides many others. He wrote also a piece entitled *De Rhetoricæ Institutione*, which is not extant.

ARNOLD, of Brescia, in Italy, distinguished himself, in the 12th century, by being the founder of a sect which opposed the wealth and power of the Roman clergy. He went into France, where he studied under the celebrated Peter Abelard. Upon his return to Italy he put on the habit of a monk, and opened his invectives in the streets of Brescia. He pointed his declamation against the bishops, the clergy, the monks, and finally against the Roman pontiff himself; to the laity only he was indulgent. In 1139 he was cited to appear before a grand council at Rome. His accusers were the bishop of Brescia, and many others, whom he had ridiculed and insulted. Nor from his judges could he look for much indulgence. He was found guilty, and sentenced to perpetual silence. Upon this he left Italy, crossed the Alps, and found a refuge in Zurich. After the death of pope Innocent II. he returned to Italy, and was ultimately condemned to death and executed in 1155. His name is chiefly deserving of being remembered for the boldness of his attempt to lower the power of the pope and his clergy, in an age when the papacy existed in all the plenitude of its power and influence.

ARNOLDISTS, in *Ecclesiastical History*, a sect so called from their leader Arnold of Brescia.

ARNOLDUS, GOTHOFREDUS, pastor and inspector of the churches of Perleberg, and historiographer to the king of Prussia, was born at Annaburg, in the mountains of Misnia, in 1666. He was a zealous defender of the Pietists, a sect among the German Protestants, and composed a great number of religious works, particularly an *Ecclesiastical History*, which exposed him to the resentment of the divines, and another giving an account of the doc-

trines and manners from the first ages, in which he frequently animadverts upon Cave's *Primitive Christianity*. He died in 1714.

ARNSTADT, a bailiwick in the principality of Schwazburg-Sanderhausen, in Germany. It contains 2 cities, 26 villages, and 5 hamlets, with 9700 inhabitants. The capital of the bailiwick is of the same name. It is divided by the river Werra into two portions, has walls, and a castle, in which a gallery of pictures is preserved, and where a porcelain manufactory is now carried on. A considerable trade is pursued in brewing, distilling, tanning, and the sale of grain. It contains 726 houses and about 4300 inhabitants. Long. 11. 3. 2. E. Lat. 50. 49. 57. N.

ARNSTEIN, a bailiwick in the circle of Lower Maine, in Bavaria, 66 square miles, or 42,200 acres, in extent. It is watered by the river Wehre, and, with the exception of 7000 acres in the southern part, which is woodland, is fruitful in corn, flax, and wine. It contains 1 city, 2 market-towns, and 37 villages, with 11,500 inhabitants. The capital of the bailiwick has the same name, and contains 350 houses, and 1800 inhabitants, who trade chiefly in wood-ware, corn, and wine.

ARNULPH, or ERNULPH, bishop of Rochester in the reign of Henry I. He was born in France, where he lived some time a monk of St Lucien de Beauvais. The monks led most irregular lives in this monastery, for which reason he resolved to quit it, but first took the advice of Lanfranc, archbishop of Canterbury, under whom he had studied in the abbey of Bec, when Lanfranc was prior of that monastery. This prelate invited him over to England, and placed him in the monastery of Canterbury, where he lived a private monk till Lanfranc's death. When Anselm came to the archiepiscopal see, Arnulph was made prior of the monastery of Canterbury, and afterwards abbot of Peterborough. In 1115 he was consecrated bishop of Rochester, which see he held nine years, and died in March 1124, aged 84. Arnulph wrote a piece in Latin concerning the foundation, endowment, charters, laws, and other things relating to the church of Rochester: it is generally known by the title of *Textus Roffensis*, and is preserved in the archives of the cathedral church of Rochester. It has been printed in Thorpe's *Registrum Roffense*.

ARNWAY, JOHN, a clergyman distinguished by his benevolence and loyalty to King Charles I., was descended from a very good family in the county of Salop, from which he inherited a considerable estate. He was educated at Oxford; and, having received holy orders, obtained the rectories of Hodnet and Ightfield, where he distinguished himself by his piety and exemplary charity; for it was his custom to clothe annually twelve poor people, and every Sunday to entertain as many at his table, not only plentifully, but with intimacy and respect. The civil war breaking out, he preached against rebellion, and raised and clothed eight troopers for the service of King Charles I., upon which his house was plundered by the parliament's army. He then went to Oxford to serve the king in person, which subjected him to a new train of misfortunes; for his estate was soon after sequestered, and himself imprisoned till the king's death; after which he went to the Hague, where he published, 1, *The Tablet*, or the Moderation of Charles I. the Martyr; and, 2, *An Alarm to the Subjects of England*. He at last went to Virginia, where he died in 1653.

AROMA PHILOSOPHORUM denotes either saffron or the aroph of Paracelsus; as *aroma Germanicum* denotes elecampane.

ARONA, a town of Italy, in the duchy of Milan, with a strong castle. It stands on the lake Maggiore. Long. 8. 25. E. Lat. 45. 41. N.

Arches ARONCHES, a town of Portugal, in Alentejo, on the confines of Spain, seated on the river Caro. It is well fortified, and contains about 500 inhabitants. Long. 5. 16. W. Lat. 14. 39. N.

AROO, an island in the Eastern Seas, 140 miles in length by about 40 in breadth, lying to the south of Papua. The Chinese merchants settled at Banda carry on a traffic with this island, from which they procure pearls, edible bird-nests, esteemed so great a delicacy by the Chinese epicures, tortoise shell, and stones. An aromatic vegetable substance called the Missoy bark is found here: it is also conjectured to be the haunt of the bird of paradise. The centre of the island is in long. 135. E. and lat. 6. S.

AROOBAY, a town of the empire of Russia, in the Ukraine, seated on the river Occa. Long. 38. 15. E. Lat. 51. 48. N.

AROPH, a contraction of *aroma philosophorum*, a name given to saffron.

AROPH Paracelsi, a name given to a kind of chemical flowers, probably of the same nature with the *Ens Veneris*, elegantly prepared by sublimation from equal quantities of lapis hæmatites and sal ammoniac.

AROSBAY, a town of the East Indies, on the coast of the island of Madura, near Java. Long. 14. 30. E. Lat. 9. 30. N.

AROURA, a Grecian measure of 50 feet. It was more frequently used for a square measure of half the plethron. The Egyptian aroura was the square of 100 feet.

ARPAGIUS, or HARPAGIUS, among the ancients, a person who died in the cradle, or at least in early youth. The word is formed from the Greek *ἀρπαζω*, *I snatch*. The Romans made no funerals for their *arpagii*. They neither burnt their bodies, nor made tombs, monuments, or epitaphs for them; which occasioned Juvenal to say,

— Terra clauditur infans
Et minor igne rogi.

In after-times it became the custom to burn such as had lived to the age of 40 days, and had cut any teeth; and these they called *Ἀρπακτοὶ* or *Ἀρπαγυμῖνοι*, q. d. *rapti*, *ravished*. The usage seems to have been borrowed from the Greeks; among whom, Eustathius assures us, it was the custom never to bury their children either by night or full day, but at the first appearance of the morning; and that they did not call their departure by the name of *death*, but by a softer appellation, *ἡμερᾶς ἀρπαγή*, importing that they were ravished by Aurora, or taken away to her embraces.

ARPHAXAD, the son of Shem and father of Salah. Arphaxad was born in the year of the world 1658, a year after the deluge, and died in the year of the world 2096, at the age of 438.

ARPINAS, or ARPINO, JOSEPH CÆSAR, a famous painter, born in the year 1560, at the castle of Arpinas, in the kingdom of Naples. He lived in great intimacy with Pope Clement VIII. who conferred upon him the honour of knighthood, and bestowed many other marks of his friendship. In the year 1600 he went to Paris with Cardinal Aldobrandin, who was sent legate to the French court on the marriage of Henry IV. with Mary of Medici. His Christian majesty gave Arpinas many considerable presents, and created him a knight of St Michael. The colouring of this painter is thought to be cold and inanimate; yet there is spirit in his designs, and his compositions have somewhat of fire and elevation. The touches of his pencil being free and bold, give therefore pleasure to connoisseurs in painting; but they are generally incorrect. What he painted of the Roman history is the most esteemed of all his works. He died at Rome in 1640.

ARPINO, a city in the kingdom of Naples and province of Terra di Lavoro. It stands on a hill washed by the Fi-

breno, is tolerably well built, possesses a good market-place and 40 churches, with 9457 inhabitants, who carry on some considerable cloth manufactories. It is celebrated as the birthplace of Marius and of Cicero. Long. 14. 12. E. Lat. 41. 44. N.

ARQUA, a town of Italy, in the Paduan, and territory of Venice, remarkable for the tomb of Petrarch. Long. 11. 43. E. Lat. 45. 43. N.

ARQUES, a town of Normandy, now in the department of the Lower Seine, in France, seated on a small river of the same name. Long. 1. 30. E. Lat. 49. 54. N.

ARRACAN. This was formerly an independent kingdom; in 1783 it became a maritime province of the Burman empire, and was added to the British possessions in that quarter by the treaty of 1826, dictated by a British army at the gates of the Burmese capital. It is bounded by the Chittagong district on the north, from which it is separated by the small river Nauf; by Pegue on the south, in lat. 18. N.; on the west by the Indian Ocean; and on the east, at the distance of about 50 miles, it is divided from Ava by a range of mountains, through which there are very few passes. It may be estimated at 230 miles in extreme length, and in breadth 50; and the coast is studded with several fertile islands, viz. Ramree, Cheduba, &c. The mountains rise to the elevation of from 3000 to 5000 feet, and decline gradually towards the east in a succession of ranges. They were crossed in 1826 by Lieutenant Trant and a detachment of sepoy, and were found to abound in springs; and it appeared that a considerable commerce had been carried on to the eastward by this route previous to the British invasion. They were crossed farther to the south by Lieutenant Browne and a party of sepoy, and the country was found perfectly wild, and one continued succession of hills, jungles, and ravines. They extend northward as far as the southern bank of the Brahmaputra. The inhabitants of these mountains are averse to mix with the natives of the plains, although the Burmans, after their conquest of Arracan, compelled many, and allowed a few settlers from their native hills, to settle in the villages, where they are treated with humanity, in order to reconcile them to the restraints of civilization. A large proportion of these mountaineers are still independent, and have uniformly rejected a foreign yoke. A range of hills, very inferior in height, skirts the shore; and the valley which lies between them is covered with thick jungles and impenetrable woods, and filled with wild animals, such as the elephant, the tiger, &c. Owing to the moist temperature (the periodical rains continuing from June to November, and often to December, besides occasional showers), this tract of country is frequently flooded, and is at all times intersected with rivers, lakes, and inlets of the sea; so that the communication between the villages must be maintained by means of boats. The soil is fertile, especially in the vicinity of the mountains; but the frequent rains and exhalations under the burning sun of the tropics are adverse to European constitutions. The staple produce is rice, for which the country is well adapted, from its moist and hot climate. The other productions are sugar, hemp, indigo, onions, garlic, turmeric. The fruits are abundant and of a superior quality, viz. pine-apples and plantains, mangoes, jacks, sweet limes, cocoa nuts, and other tropical fruits. The forests produce excellent timber; and the teak tree is found, but in such inaccessible parts, that it is usually imported from Rangoon. The rivers wash down from the mountains gold and silver particles, for the liberty of collecting which a certain rent is paid. Salt is produced in great abundance. Limestone is also procured from the islands that lie along the shore. The greater portion of the country is in a state of nature; and it is estimated by Hamilton, the accurate and well-

Arqua
||
Arracan.

Arracan. informed writer of the *East India Gazetteer*, that not above 400 square miles of this extensive territory are under cultivation. The inhabitants do not exceed 100,000, consisting chiefly of a rude and filthy race called the Mughs, about one third being Mahometans, and not more than one tenth Burmese. They speak their own language, which is different from the Burmese tongue; the principal Mahometans use the language of Hindostan, and the lower orders a mixed dialect.

The Mughs appear in their habits to be not far removed from the savage state. They give no attention to agriculture, but live by hunting, fishing, traffic, and rapine. They follow in their religion the Buddhist doctrines, with many Hindoo superstitions, and offer bloody sacrifices to the deities of the rivers, woods, and mountains. They are barbarous in their domestic manners, trafficking without restraint in slaves, and even pawning their wives when they are in want of money. Some bury their dead in coffins richly gilt, and others burn them. They are of a middling stature, but of a robust make, with broad faces, high and wide cheek-bones, flat noses, and, in the obliquity of their eyes, resembling the Chinese. They are so far addicted to the notions of the Hindoos that they scruple about taking the life of an animal; but when dead they eat every species of animal without restraint, and are of the most disgusting and filthy habits in their eating as well as in their persons. Besides the tribes on the sea-coast, there are many rude tribes scattered in the interior, and beyond its limits to the east, as well as those of Chittagong. These different tribes are frequently engaged in mutual hostilities. It has been from time immemorial the practice of these Mughs, like most of the other barbarous nations of Asia, to make predatory inroads on the southern parts of Bengal, and to carry off all the booty which they could collect, including men, women, and children, who are sold for slaves. They have even had the boldness to descend on the coast of Chittagong, to proceed into the country, plunder and burn the villages, destroy what they could not carry away, and make slaves of the inhabitants. It was to an incursion of this sort in 1777 that we owe our first knowledge of this country. In February 1776 it is mentioned by Major R. E. Roberts,¹ who was residing at Islaamabad, that a body of them made an inroad on the southern parts of Bengal, and carried off about 1800 men, women, and children, who were brought to Arracan, where the rajah was allowed his choice from the female captives; after which the remainder were conducted with ropes about their necks to the market-place, and being there sold, were employed in the cultivation of the lands and other laborious employments. It was from some of those captives who escaped that any information was obtained of this eastern country.

Before the province of Chittagong was ceded to the company, the British territories were frequently exposed to the inroads of these plunderers, and an immense expense was incurred in maintaining a sea and land force to repel them; and there are still vestiges of a fortification round the town of Islaamabad, which was raised up by the inhabitants as a defence against their inroads. Even the possession of the province of Chittagong, owing to the extent of its coast, did not wholly prevent their attacks; and a considerable force was still found necessary for the protection of the company's territories, which were from time to time molested by their hostile incursions; and Major R. E. Roberts, in an account of Arracan, published in the *Asiatic Miscellany* at Calcutta in 1777, observes, with a

singularly penetrating and almost prophetic spirit, when he is pointing out the impolicy of merely acting on the defensive against these marauders, "The longer they continue unattacked the more powerful and outrageous they will become, till at last it will be found necessary, for the immediate preservation of all the southern parts of Bengal, to enter into an expensive and perhaps bloody war with them."

Arracan, from the character of its inhabitants, who are rude and indolent, possesses no surplus produce with which to trade to other countries; and salt is the only article of export. This country was formerly the medium of commercial intercourse between Asia and Hindostan, exporting to the former European goods, such as velvet, broad cloths, piece goods, silks, muslins, betel-nut, salt, &c., and receiving in return ivory, silver, copper, sugar, tobacco, oil, and lacquered ware. The country being so poor and unproductive, produces only about 220 rupees of revenue, which will hardly defray the expense of its civil and military establishments; and it is retained, not for profit, but as an outpost of defence against the incursions and growing power of the Burmese empire.

The natives of Arracan trace their history as far back as A. D. 701, and give a lineal succession of 120 native princes down to modern times. According to them their empire had at one time far wider limits, and extended over Ava, part of China, and the Bengal territories. This extension of their empire does not agree with any known facts in history. At different times the Moguls and Peguers carried their arms into the heart of the country. The Portuguese, during the era of their greatness in Asia, gained a temporary establishment in Arracan. But in 1783 the province, with all its dependencies, was finally conquered by the Burmese; and though the inhabitants made desperate efforts to recover their independence, they were always foiled by the discipline and numbers of their enemies, who contrived to extract from this ill-cultivated tract a surplus revenue of 18,000 rupees. In 1825 the British army in Arracan became a prey to the destructive climate, and died in great numbers; and it has since proved equally injurious to the native regiments stationed on the coast.

ARRACAN, the capital of the above province, situated on a river of the same name, about 40 miles from the sea. The town is chiefly built of bamboo huts, and stands in a valley surrounded by hills, and covered with marshes and canals, communicating with a number of small streams, running between low muddy banks. The tide overflows to a considerable extent the flat borders of the river Arracan, and by its reflux converts these into a pestilential swamp, on which a great part of the town of Arracan is built. In such an unfavourable situation, it is necessary to drive wooden posts into the ground to obtain a foundation for the houses, under which the water flows. We need not wonder that a place so situated should be unhealthy for Europeans. The town is perpetually involved in the putrid exhalations from these swamps, which are a perpetual source of disease. Where the ground is not swampy it consists of a soft species of rock. The surrounding ground is irregularly diversified by hills, connected by narrow ridges, and separated by ravines, either occupied by a stream or a marsh. The houses are connected by wooden bridges; and in its centre is a square surrounded by a wall containing pagodas and images of Gaudma, of all sizes, from an inch to 20 feet in height. The town and fort were taken by the Burmese in 1783.

¹ *Asiatic Annual Register*, vol. i.

Arrack It was taken by the British army in 1825, and was found to be in a most miserable condition, and the air most pestilential.

Arrack ARRACK, a spirituous liquor manufactured at several places in the East Indies, namely, Goa, Columbo, and Batavia. In India every kind of spirituous liquor is known under the general appellation of arrack; and hence the various accounts given of the mode of making it, and the materials used. English gin is called by the natives English arrack,—and it is certain that the several kinds of arrack differ as much in flavour as brandy, rum, or any other spirituous liquor. The manufacture of arrack was formerly carried on by the Portuguese at Goa, but the art of making it has been transferred for the most part from that place to Batavia.

Goa and Batavia are the chief places for arrack. At Goa there are divers kinds; single, double, and treble distilled. The double distilled, which is that commonly sent abroad, is but a weak spirit in comparison with Batavia arrack; yet, on account of its peculiar and agreeable flavour, is preferred to all the other arracks of India. This flavour is attributed to the earthen vessels which they use at Goa to draw the spirit; whereas at Batavia they use copper stills.

The Parier arrack made at Madras, and the Columbo and Quilone arrack at other places, being fiery, hot spirits, are little valued by the Europeans, and therefore rarely imported, though highly prized among the natives. In the best Goa arrack, the spirits of the cocoa juice do not make above a sixth or eighth part.

The Goa arrack is invariably made from a vegetable juice called toddy, which flows by incision from the cocoa-nut tree. When a sufficient quantity of toddy is procured, it is left to ferment, which it soon does. When the fermentation is over, and the liquor or wash is become a little tart, it is put into the still; and a fire being made, the still is suffered to work as long as that which comes over has any considerable taste of spirit. The liquor thus procured is the low wine of arrack; and this is so poor a liquor, that it will soon corrupt and spoil if not distilled again, to separate some of its phlegm; they therefore immediately after pour back this low wine into the still, and rectify it to that very weak kind of proof spirit, in which state we find it. The arrack we meet with, notwithstanding its being of a proof test, according to the way of judging by the crown of bubbles, holds but a sixth, and sometimes but an eighth part of alcohol, or pure spirit; whereas our other spirits, when they show that proof, are generally esteemed to hold one half pure spirit.

Batavia arrack is obtained by distillation from rice and sugar. A hot, fiery spirit is imported into Batavia by the Chinese Junks, called samsheew, which is mixed with arrack, and which is chiefly consumed by the Chinese who reside in that settlement.

The following are the East India Company's regulations for shipping arrack, &c. No arrack or other spirits are permitted to be shipped in India or China in any of the Company's ships returning to Europe, except for the use of the ship's company on the voyage, or in the immediate privilege of the commander and officers. Each cask or chest shipped for the use of the ship's company must be marked "stores;" and those shipped on the private account of any of the officers shall be marked with the name at length of the person to whom it belongs; and such casks or chests as shall not be so marked shall be taken and deemed to be the property of the commander. The tonnage of arrack is calculated at 252 gallons per ton.

ARRAGON. See ARAGON.

ARRAIGNMENT, in *Law*, the arraigning or setting a thing in order, as a person is said to arraign a writ of

novel disseisin, who prepares and fits it for trial; but this term more properly denotes the calling of a person to answer in form of law upon an indictment, &c.

ARRAN, an island on the west coast of Scotland, near the mouth of the river Clyde, which forms part of the county of Bute. It is about 20 miles in length by from 8 to 11 in breadth, and contains a superficial area of 165 square miles, or 105,814 acres, of which about 14,431 are cultivated. This island is of an extremely rugged and mountainous surface, particularly in the northern part, in which the valleys are deep and romantic. The principal mountain is Goatfell, which rises, according to accurate measurement, 2685 feet above the level of the sea, and is clothed with lichens and mosses. A few others approach to the same elevation. There are five small lakes in the island, from which two streams have their source. The quadrupeds are not numerous. There are a few red deer, the remains of a numerous breed, which are said still to find shelter among the mountains; and wild goats are still harboured in those parts. The cattle and sheep, which were formerly small, have been improved by the introduction of a larger breed. The birds are eagles, hooded crows, plovers, curlews, black cock, and other species of grouse, which are exceedingly numerous in the mountains. Ptarmigans, which were formerly seen, have now disappeared. Limestone, marl, and slate, are found in different parts, and there are also indications of coal; while in the mountains are found marble, jasper, agates, cairngorms, and a fine species of rock-crystal called the Arran diamond. Shoals of herring frequent the shores, and the herring fishery is prosecuted to a great extent. No less than 200 fishing vessels, well manned and properly fitted out, and belonging to the island, are employed in it. Arran has two remarkably fine harbours, Lamash on the east side, and Loch Ranza on the other. Formerly the style of agriculture was extremely rude and imperfect; but the improved system has now been adopted in all its branches. Most of the high land was at one time a common, on which the cattle of all the tenants was indiscriminately pastured. The whole of the cultivated land is now subdivided and inclosed, and the hills laid out in sheep-walks. Flax is cultivated in small quantities, and linens and some woollens are manufactured. With the exception of a few farms, the whole island belongs to the Duke of Hamilton, who has very lately begun to take an interest in its improvement, and expended a considerable sum in making roads, bridges, and small harbours. It has several castles of great antiquity; one, the castle of Brodick, which was garrisoned by Sir J. Hawkins in the reign of Edward II.; another at Lochvanza, built by Robert II. as a hunting seat. Population 6754.

ARRAS, an arrondissement in the Pas de Calais, in France, extending over 552 square miles, or 353,280 acres. It is divided into nine cantons, and these into 218 communes, containing 143,615 inhabitants. The chief city of the arrondissement has the same name. It is situated at the influx of the Erinchon into the navigable river Scarpe. It is regularly fortified with a citadel, built by Vauban, with bomb-proof casemates. The city is well built, with regular and lofty houses. The cathedral is a sumptuous Gothic edifice, besides which there are twelve parish churches, the Abbey of St Wast, now the barracks, and some other fine public edifices. The inhabitants, 19,498 in number, are generally very industrious, and carry on extensive manufactories of fine linen and of lace, besides which there are establishments for refining sugar, for making soap, salt, starch, several breweries, and mills for spinning cotton. The manufactories have, however, declined considerably since the peace. It is the birthplace of the as-

Arreoyoys.

sassin Damiens, and of the two brothers Robespierre. It is in long. 2. 50. 54. E. and lat. 50. 17. 37. N.

ARRAY, in *Law*, the ranking or setting forth of a jury, or inquest of men impannelled on a cause.

ARRAYERS, ARRAGERS, or ARRAITORES, is used in some ancient statutes for such officers as had care of the soldiers' armour, and saw them duly accoutred in their kinds. In some reigns commissioners were appointed for this purpose.

ARRENTATION, in the forest laws, implies the licensing the owner of lands in a forest to inclose them with a low hedge and a small ditch, in consideration of a yearly rent.

ARREOYS. Among the more singular secret societies which mankind have formed, is one in Otaheite and the neighbouring islands for the destruction of their own species, called *Arreoy*, *Arehoe*, or *Earowie*; and it is not a little remarkable that it should subsist among tribes distinguished for courteousness and humanity. We read in the older authors that there is an absolute prohibition against the females of Formosa rearing children before the age of thirty-six, though it does not appear that there is any limitation as to the age at which their espousals may take place. But in the event of pregnancy, it is necessary that abortion should follow, which is accomplished by the aid of the priestesses of the island. Among the Arreoyoys, however, extirpation of the infant being constitutes the leading feature of their ordinances.

Whether Mendana, Quiros, and the earlier navigators of the South Pacific Ocean, discovered this society, does not appear: it has, at any rate, been reserved for those of later date to unfold its principles and peculiarities, though, indeed, its constitution is still enveloped in much mystery, the members being bound to the strictest secrecy.

The society of Arreoyoys consists of hundreds or perhaps thousands of both sexes, who engage to destroy their own offspring at the moment of birth. It is chiefly composed of persons distinguished by valour and merit, and hence one or more individuals of each family of the chiefs are of the number. It has been remarked, that all the men profess themselves warriors, and are in general stout and well made; that the greatest trust and confidence are reposed in them; and it rather appears that the women consist of the higher ranks only. There are different gradations in this community, which are to be recognised from the mode of tattooing: the more profusely the men are tattooed, the higher is their rank in society; the first are called *Ava bly areema tutove*; 2, *Areema bly*; 3, *Ahowhoa*; 4, *Harrotea*; 5, *Eote ole*; 6, 7, *Po*; and youths training up are designated *Mo*; but the meaning of these names is not explained. By the fundamental laws of the society, the offspring must be destroyed, yet it is not known with certainty by whom or in what particular manner; the murder is always perpetrated in secret, probably by strangulation; all the attendants are excluded; for it is said, were they to witness it they would be adjudged guilty of participation, and put to death. Sometimes the mother, animated by natural affection, tries to preserve her infant, and resists the persuasions of her husband and his brother Arreoyoys, who wish to consign it to destruction. But in general the enormity of the crime does not appal the females, though they are described to be affectionate and tender. We find a dancing girl pregnant by an Arreoy expressing herself thus to the English navigators: "Perhaps the *Etooa* or deity of England might be offended with the practices of the Arreoyoys, but her own was not displeased with them. However, she promised if we would come from England for her child, she might perhaps keep it alive, provided we gave her a hatchet, a shirt, and some

red feathers." That the rules of the community are very strict, may be inferred from an instance given by Captain Bligh. A chief, a member of the society, married a sister of the king of Otaheite, by whom he had eight children, and the whole were destroyed at their birth! Nor did this enormity seem to originate from any other source, as the parents afterwards adopted a nephew as their heir.

It may here be observed, that there are other practices among these people regarding infanticide, which, though we want materials for positively affirming the fact, may perhaps be connected with the institutions of the Arreoyoys. When an Otaheitan chief has a child by a woman of the lower orders, it is never suffered to live; and the like seems to take place reciprocally among the higher ranks of females. The king and queen of Otaheite having ceased to cohabit, he had taken another wife, and she associated with one of her attendants of low rank. When pregnant, the missionaries endeavoured to persuade her to spare her child, which she said she would have done had it been her husband's, but now it would be base-born, and must perish; and she resisted all entreaties to the contrary. Afterwards, having visited them, she excused herself for having put the infant to death, stating that it was the custom of the country to murder all base-born children, and hers being by a low man, she had only complied with the usual practice. Indeed it is affirmed by the missionaries who visited that island in 1797 to be a common proceeding among all ranks to strangle infants the moment they are born. "A perpetrator of this horrid act," the narrator observes, "was among those whom curiosity attracted to visit us. She was a good-looking woman, and esteemed by the natives a great beauty, which I suppose to be the inducement that tempted her to murder her child; for here the number of women bearing no proportion to the men, those esteemed handsome were courted with great gifts, and got so accustomed to change their husbands, to go with them from place to place; and run after the diversions of the island, that rather than be debarred those pleasures, they stifle a parent's feelings, and murder their tender children." Thus many hundreds born into the world are never suffered to see the light; and so little criminality in the opinion of the natives is attached to the deed, that many women disclose the number they have put to death without scruple. It has been calculated that at least two thirds of the births on the island perish in this manner.

The Arreoyoys enjoy great privileges, and are everywhere united by the reciprocal ties of friendship and hospitality. When they visit different islands, they receive presents, and are entertained with feasting and dramatic exhibitions; and all this they seem to expect rather as a matter of right than of courtesy. Their clothes are of the finest materials. They pass their time in luxurious idleness, perfuming their hair with fragrant oils, singing and playing on the flute, and passing from one amusement to another. "Wherever they go," says Forster, "the train of sensual pleasure awaits them." They feast on the choicest vegetables; and an abundance of dogs' flesh and poultry are liberally provided by the lower classes for their entertainment. They are copiously supplied with *kava*; and for them are performed nocturnal sports of music and lascivious dances, to which no other spectators are admitted. Their presence seems to enliven the whole country; and among the various entertainments to which it gives birth, is one called *hopoupah*, of a dramatic nature, in which they themselves act a part. As soon as one Arreoy visits another, though a stranger, he immediately has his wants supplied and his wishes gratified; he is introduced to other members, who vie with each other in loading him with courtesies and presents. They are of all others the

Arreoyoys.

Arreys. most luxurious and profuse, often consuming the whole provisions of a district. When Captain Cook lay at Huahine, no less than 70 canoes were observed crossing over to another island with 700 Arreos on board; and thus they keep great meetings at appointed times, and travel in companies from one island to another. It has been affirmed, but perhaps without sufficient foundation, that a promiscuous intercourse of the sexes prevails in their society; however, they are permitted great latitude in their amours, except in times of danger, as almost all are fighting men. Sufficient inducements are, therefore, held out to be admitted into this mysterious community.

Any one may withdraw at pleasure from the society; and an example is given of a chief who had killed his first-born child, but preserved the second, having withdrawn in the interval. A woman who ceases to be an Arreoy incurs a reproachful name, signifying "bearer of children." Thus, while in most other countries the name of parent confers honour and respect, among the Arreos of Otaheite it is used as a term of contempt and reproach. A chief of some repute, hearing that the king of Great Britain had a numerous offspring, declared that "he thought himself a much greater man, because he belonged to the Arreos."

With respect to the origin of this society, Forster was the first to offer any conjectures. "In a country," says he, "which has emerged so lately from barbarism as Otaheite, we cannot suppose that such a community, which is evidently injurious to the rest of the nation, would have maintained itself to the present time, were not its advantages so considerable as to require its continuance." There are two causes, he adds, which favour the existence of the Arreos; first, the necessity for entertaining a body of warriors to defend their fellow-citizens from the invasions and depredations of enemies; secondly, it was necessary, by such an association, to prevent the too rapid increase of the number of their chiefs. "Perhaps," he remarks, "some intelligent Otaheitan lawgiver might foresee that the common people would at length groan under the yoke of such petty tyrants, whose number was ever multiplying." The ordinary practice of infanticide is ascribed by Mr Wilson, who visited the South Seas in 1801, merely to the love of pleasure and avarice, which latter passion had gained great ascendancy since the intercourse of the islanders with Europeans: "being well aware," says he, "that the beauty of females rearing families experiences an earlier decay, it is anxiously preserved for their visitors, by destruction of their offspring, or even by procuring abortion." Before offering any opinion on this point, we shall notice a custom in the northwest of India somewhat analogous, which also is attended with mystery.

Amongst certain tribes called Jarejahs, which are more particularly disseminated in the peninsula of Guzerat, the whole females are devoted to death at the moment of their birth. But this is in consequence of general custom, not of any special association. The immediate death of a daughter is viewed as the inevitable consequence of its birth; and the innocent beings falling a sacrifice to this barbarous ordinance yearly amount to many thousands. When a woman is delivered of a daughter, the event is communicated by the female attendants to the father, who desires them to do as is customary; an injunction said to be followed by the mother applying a little opium on the nipple of her breast, which is sucked in by the child. More usually it is strangled by herself, or drowned in a basin of milk; but women of rank, who have attendants, never perform the office themselves. However, from the mystery observed, it is, as among the Arreos, difficult to obtain correct information. In some districts,

any of the female attendants may put the infant to death; in others, a kind of domestic priest becomes the executioner; and the infant being placed naked in a small basket, it is carried out to be interred, for which he receives a trifling fee. Among the Arreos, those who preserve their children seem to suffer a degree of degradation; and they plead as an apology for their destruction, that it is necessary to preserve the privileges of their tribe. With the Jarejahs, the father is obeyed on signifying his desire for preservation; but if he continues silent on receiving the intelligence, the usual custom must be complied with. The mother is generally averse to the sacrifice, but her scruples to preserve her offspring are seldom attended to; should a short interval elapse, however, before the bloody deed is done, it then becomes unlawful, and the child must be spared.

Perhaps the murderous practices of the Arreos in the South Sea islands may have originated in some religious principle. At the same time, it appears that, in the ordinary destruction of infants by the islanders of the South Pacific Ocean, there is nothing of a sacrificial nature; for though they do not suppose that their displeasure is thereby incurred, they do not pretend that the practice is acceptable to any of their divinities. Mr Malthus, we may add, ascribes the origin of the Arreoy institutions to a superabundance of population, and the necessity of adopting some forcible expedients to bring it within the limits of subsistence. (See Forster's *Voyage*, vol. ii.; Cook's *First and Second Voyages*; Bligh's *Voyage*; *Missionary Voyage*; Hamilton's *Account of the Loss of the Pandora*.)

ARREST, in *English Law* (from the French word *arrest*, to stop or stay), is the restraint of a man's person, obliging him to be obedient to the law, and is defined to be the execution of the command of some court of record or office of justice. Arrests are either in *civil* or *criminal* cases. 1st, An arrest in a *civil cause* is defined to be the apprehending or restraining one's person by process, in execution of the command of some court. 2d, An arrest in a *criminal cause* is the apprehending or restraining one's person in order to be forthcoming to answer an alleged crime.

Arrests by private persons are in some cases commanded. Persons present at the committing of a felony must use their endeavours to apprehend the offender, under penalty of fine and imprisonment; and they are also, with the utmost diligence, to pursue and endeavour to take all those who shall be guilty thereof out of their view, upon a hue and cry levied against them. By the vagrant act, 17 Geo. II. cap. 5, every person may apprehend beggars and vagrants; and every private person is bound to assist an officer requiring him to apprehend a felon.

In some cases, likewise, arrests by private persons are rewarded by law. By the 4 and 5 William and Mary, cap. 8, persons apprehending highwaymen, and prosecuting them to a conviction, are entitled to a reward of L40; and if they are killed in the attempt, their executors, &c. are entitled to the like reward. By the 6 and 7 William III. cap. 17, persons apprehending counterfeiters and clippers of the coin, and prosecuting them to conviction, are entitled to L40.

By 5 Anne, cap. 31, persons who shall take any one guilty of burglary, or the felonious breaking and entering any house in the daytime, and prosecute them to conviction, shall receive the sum of L40, within one month after such conviction.

With regard to arrests by public officers, as watchmen, constables, &c. they are either made by their own authority, which differs but very little from the power of a private person; or they are made by a warrant from a justice of peace.

Arrest.

Arrest-
ment
||
Arsamas.

ARREST of Judgment, in *Law*, is the assigning just reason why judgment should not pass; as, want of notice of the trial; a material defect in the pleading; when the record differs from the deed impleaded; when persons are misnamed; where more is given by the verdict than is laid in the declaration, &c.

ARRESTMENT, in *Scots Law*, denotes that diligence by which a creditor detains the goods or effects of his debtor in the hands of third parties till the debt due to him shall be paid.

ARRHABONARII, a sect of Christians, who held that the eucharist is neither the real flesh nor blood of Christ, nor yet the sign of them; but only the pledge or earnest thereof.

ARRHEPHORIA, a feast among the Athenians, instituted in honour of Minerva, and of Herse, daughter of Cecrops.

ARRIAN, a philosopher and historian, who flourished in the time of the emperor Adrian and the two Antonines, was born at Nicomedia in Bithynia. His learning and eloquence procured him the title of *The Second Xenophon*, and raised him to the most considerable dignities at Rome, even the consulship itself. Many of his pieces have been lost. Of his dissertations upon Epictetus, there have been preserved four of the eight books which he wrote. His history of the expeditions of Alexander the Great, in seven books, is the most valuable of his remains. The work entitled the *Periplus of the Red Sea* has been ascribed to him by many, but, as Dr Vincent contends, erroneously. (See VINCENT, Dr William.) The best editions of Arrian are those of Gronovius and Schneider; the one published in 1704, the other in 1798.

ARRIEGO, a department of France, bounded on the east by Aude, on the south-east by the Eastern Pyrenees, on the south by the mountains, and on the west and north by the department of the Upper Garonne. Its extent is 244 square miles, or 143,360 acres. It sends two deputies to the Chamber, is in the diocese of Pamiers, and within the jurisdiction of the royal tribunal of Toulouse. It contains three arrondissements, 20 cantons, and 330 communes. The population by the last returns appears to be 229,760 inhabitants. The chief towns are Tarascon, Aix, and Mirepoix.

ARROE, a small but very fruitful island in the Baltic, to the south-west of Funen. Its greatest length is three Swedish miles, but its breadth is not more than half a mile. It belongs to the duchy of Sleswick, and came definitively to the crown of Denmark in the year 1749. Fire-wood is scarce, as every spot of ground is under tillage. The horses and black cattle are in good condition. Agriculture, navigation, and fishing, are the chief sources of income. Population above 4500. Long. 10. 20. E. Lat. 54. 53. N.

ARROYO DEL PUERTO, a town of Spain, on the Ayuda, in the province of Estremadura, containing 5000 inhabitants. There is a pottery here, which employs 52 workmen, and furnishes 208,000 pieces of ware annually.

ARROW, a missile weapon of offence, slender pointed and barbed, to be cast or shot with a bow. See ARCHERY.

Arrow-Makers are called *fletchers*, and were formerly, as well as bowyers, persons of great consequence in the commonwealth.

ARSACES, otherwise *MITHRIDATES*, a king of the Parthians, spoken of in the first book of Maccabees. He considerably enlarged the kingdom of Parthia by his good conduct and valour.

ARSAMAS, a circle of the Russian government of Nishegorod, between long. 43. 21. and 44. 10. E. and lat. 54. 37. and 55. 28. N. It is watered by the rivers Tescha and Scholka, which flow to the Volga. It is an undulat-

ing country; much of it is covered with wood, and some part of it with swamps; but it produces flax in abundance, and corn sufficient for the use of the inhabitants, who amount to 120,000, of whom 4351 are slaves belonging to the crown, and 23,643 belonging to other individual nobles. The chief employment is wood-cutting, potash burning, and spinning linen yarn.

ARSAMAS, the capital of the Russian circle of the same name, at the junction of the river Scholka with the Tescha. It is an old and ill-built city, with 20 wood and 2 stone churches, some other public buildings, 1416 houses, and about 8000 inhabitants. There are some manufactures of the leather peculiar to Russia, of soap, and of woad; and many shoes are made for distant markets. The merchants deal largely in linen and sail-cloth. It is in lat. 55. 27. N. and long. 43. 46. E.

ARSENAL, a royal or public magazine, or place appointed for the making and keeping of arms necessary either for defence or assault. Some derive this word from *arx*, a *fortress*; others from *ars*, denoting a *machine*; others again from *arx* and *senatus*, because this was the defence of the senate; but the more probable opinion derives it from the Arabic *darsenaa*, which signifies *arsenal*. The arsenal of Venice is the place where the galleys are built and laid up. The arsenal of Paris is that where the cannon or great guns are cast.

ARSENIUS, a deacon of the Roman church, of great learning and piety. He was appointed by the pope to go to the emperor Theodosius, as tutor to his son Arcadius. Arsenius arrived at Constantinople in the year 383. The emperor happening one day to go into the room where he was instructing Arcadius, his son was seated and the preceptor standing. At this he was exceedingly displeased, took from his son the imperial ornaments, made Arsenius sit in his place, and ordered Arcadius for the future to receive his lessons standing uncovered. Arcadius, however, profited little by his tutor's instructions, for some time after he formed a design of dispatching him. The officer to whom Arcadius had applied for this purpose divulged the affair to Arsenius, who retired to the deserts of Scete, where he passed many years in the exercises of the most strict and fervent devotion. He died there, at 95 years of age.

ARSHOT, a town of the Austrian Netherlands, situated about 14 miles east of the city of Mechlin, in long. 4. 45. E. lat. 51. 5. N.

ARSON, in *English Law*, is the malicious and wilful burning of the house or outhouse of another man; which is felony at common law.

ARSURA, in ancient customs, a term used for the melting of gold or silver, either to refine them or to examine their value. The method of doing this is explained at large in the Black Book of the Exchequer, ascribed to Gervaise, in the chapter *De Officio Militis Argentarii*, being in those days of great use, on account of the various places and different manners in which the king's money was paid.

ARSURA is also used for the loss or diminution of the metal in the trial. In this sense a pound was said *tot ardere denarios*, to lose so many pennyweights.

ARSURA is likewise used for the dust and sweepings of silversmiths, and others who work in silver melted down.

ARTA, or *LARTA*, a town of Lower Albania, in European Turkey, containing about 6000 inhabitants, Turks and Christians, who carry on a trade in cattle, wine, tobacco, cotton, flax, pulse, fur, leather, wheat, &c. They also manufacture cotton and woollen stuffs. Arta is situated about 9 miles from the gulf to which it gives name, otherwise called Prevesa. Long. 21. 8. E. Lat. 39. 30. N.

ARTABA, an ancient measure of capacity used by the

Arsama
||
Art.

Artaxius Persians, Medes, and Egyptians. The Persian artaba is represented by Herodotus as larger than the Attic medimnus by three Attic chœnixes: from which it appears that it was equal to $6\frac{1}{4}$ Roman modii; consequently it contained $166\frac{2}{3}$ pounds of wine or water, or $126\frac{2}{3}$ pounds of wheat. The Egyptian artaba contained five Roman modii, and fell short of the Attic medimnus by one modius; it consequently held $133\frac{1}{3}$ pounds of water or wine, or 100 pounds of wheat.

ARTABAZUS, the son of Pharnaces, commander of the Parthians and Chorasmians in the famous expedition of Xerxes. After the battle of Salamis he escorted his sovereign to the Hellespont with 60,000 chosen men; and after the battle of Plataea, in which Mardonius engaged in opposition to his wishes and advice, he made a noble retreat into Asia with 40,000 men under his command.

ARTAXERXES, the name of several kings of Persia. See PERSIA.

ARTEDI, PETER, an eminent naturalist, was born in Sweden in the year 1705, in the province of Angermania. Although his parents were poor, yet it appears they found means to give him a liberal education, and with this view sent him to the college of Hurnesand. Intending to embrace the ecclesiastical profession, he went in 1724 to Upsal; but he turned his attention to medicine from the strong bent of his mind for the study of natural history, in which science he made rapid progress, and soon rose to considerable eminence, particularly in the department of ichthyology. Confining his botanical studies to the umbelliferous plants, he suggested a new mode of classification. But Artedi was much better acquainted with chemistry than botany. His attention, however, was chiefly directed to ichthyology, the classification of which he greatly reformed, and new-modelled upon philosophical principles. This arrangement added greatly to his reputation as a naturalist at the time, and afterwards became popular over Europe. In 1728 his celebrated countryman Linnæus arrived in Upsal, having been appointed to deliver lectures on botany in that place; and so high stood the character of Artedi as a philosopher, that a lasting friendship was formed between these two great men. In 1732 both left Upsal; Artedi for England, in pursuit of his favourite study, and Linnæus for Lapland, to examine its natural productions; but before parting, they reciprocally bequeathed to each other their manuscripts and books upon the event of death. However, in the year 1735 they met again at Leyden, where Artedi was introduced to Seba, and employed in preparing for the press the third volume of that eminent naturalist's *Thesaurus*, which chiefly related to fishes. Artedi formed the resolution, as soon as that work was finished, to return to his native country, and publish the fruits of his own labours; but as he was returning home from Seba's house on the evening of the 27th September 1735, the night being dark, he fell into the canal and was unfortunately drowned. According to agreement, his manuscripts came into the hands of Linnæus, and his *Bibliotheca Ichthyologica* and *Philosophia Ichthyologica*, together with a life of the author, were published at Leyden in the year 1738.

ARTEMIDÓRUS, famous for his Treatise on Dreams, was born at Ephesus, and lived under the emperor Antoninus Pius. He styled himself the *Ephesian* in all his performances but that on Dreams, where he took the cognomen of Daldianus, in compliment to his mother country Daltis. On this work he expended vast labour, not only possessing himself of all that had been written on the subject, but travelling for years in search of fortune-tellers, as well as corresponding with them in various parts, and collecting information on old dreams, and the events which were said to have followed them. It consisted of five books,

and, though abounding in frivolous observations, contained others that were interesting. It was first printed in Greek at Venice in 1518; and Rigaltius published an edition at Paris, in Greek and Latin, in 1603, to which he added some notes. Artemidorus wrote also a treatise upon Auguries, and another upon Chiromancy, but they are not now extant.

ARTEMISIA, wife of Mausolus, king of Caria, has immortalized herself by the honours which she paid to the memory of her husband. She built for him, in Halicarnassus, a very magnificent tomb, called the *Mausoleum*, which was one of the seven wonders of the world, and from which the title of *Mausoleum* was afterwards given to all tombs remarkable for their grandeur; but she died of regret and sorrow before it was finished. She appointed panegyrics to be made in honour of him, and proposed a prize of great value for the person who should compose the best. She died about the end of the 106th Olympiad, 351 years before the Christian era.

ARTEMISIA, queen of Caria, and daughter of Ligdamis, marched in person in the expedition of Xerxes against the Greeks, and performed wonders in the sea-fight near Salamis, 480 years before the Christian era. She was passionately fond of a man named Dardanus, of Abydos; but, enraged at his neglect of her, she put out his eyes while he was asleep. The gods punished her for this, by increasing the passion she entertained for him; so that the oracle having advised her to go to Leucas, which was the usage of desperate lovers, she took the leap from thence, and was interred at that place. Many writers confound this Artemisia with the former, the wife of Mausolus.

ARTEMISIUM, in *Ancient Geography*, a promontory on the north-east of Eubœa (called *Leon* and *Cale Acte* by Ptolemy), memorable for the first sea engagements between the Greeks and Xerxes.

ARTHUR, the celebrated hero of the Britons, is said to have been the son of Uthor Pendragon, king of Britain, and to have been born in 501. His life is a continued series of wonders. It is said that he killed 470 Saxons with his own hand in one day; and, after having subdued many mighty nations, and instituted the order of the Knights of the Round Table, died A. D. 542, of wounds which he received in battle. The most particular detail of his story and his exploits is that given by Geoffroy of Monmouth; but there the probable is so blended with the marvellous and extravagant, that not only the truth of the whole, but even the reality of Arthur's existence, has been called in question. In this controversy Mr Whittaker has taken much pains, in his *History of Manchester*, to vindicate the existence, and discriminate between the real and the fabulous transactions, of the British worthy. But a severe critic might be apt to say that it requires much faith in the author's judgment, not to suspect that he sometimes allows too much scope to fancy and conjecture. According to Mr Whittaker, Arthur's principal exploits were against the northern Saxons, whilst he was only prince of the Silures, and Ambrosius was the dictator or pendragon of the Britons. "In a series probably of five campaigns, and in a succession certainly of eleven victories, this great commander had repelled the Saxons from the north of Flavia, dislodged them from all Maxima, and dispossessed them of all Valentia. And these were successes so unchequered with misfortunes, so great in themselves, and so beneficial to the public, that the name of Arthur claims the first rank in the list of military, and the better one of patriot, heroes." The twelfth battle of Arthur was fought in the south of England, after he was elected to the pendragonship, against Cerdic the Saxon. "This," says Mr Whittaker, "was a most extraordinary victory, and completes the circle of Arthur's military glories." In

the author's account of this prince's conduct in peace, he asserts, that "Arthur saw that an appointment was wanted, which should at once be a more regular and more honourable signature of merit—by the certainty of the honour and the greatness of the dignity, call out all the worth of all the worthy in the nation, and collect it round the throne of the pendragon. Accordingly he established a military order. It was the first that had ever been instituted in the island; and it has since been imitated by all the nations on the continent. By means of this association, Arthur raised among the provincials a general glow of ingenuous heroism, the first spirit of chivalry that ever appeared in Europe; that manly and honourable gallantry of soul, which has made him and his worthies the subject of romantic histories over all the west of it. By this, and this alone, could he have been what history represents him, the Reverend Father of the British Heroes in general, even to the conclusion of the sixth century, and nearly the middle of the seventh. The order naturally survived its founder; and the members of it were denominated the Warriors of Arthur, though the persons were born half a century after his death."

ARTHUR'S SEAT, a high hill in the neighbourhood of Edinburgh, said to have been so denominated from a tradition that King Arthur surveyed the country from its summit, and also defeated the Saxons in its neighbourhood. It rises by a steep ascent, till it terminates in a rocky point about 810 feet high from the base. The traveller may here sit and survey at his ease the centre of the kingdom, besides having a complete view of Edinburgh, on which he looks down as if seated among the clouds. The whole forms a landscape sublime, various, and beautiful, in a very high degree.

ARTICLE, in *Grammar*, denotes a particle used in most languages for the declining of nouns, and denoting the several cases and genders thereof. The use of articles arises chiefly from this, that in languages which have no different terminations to express the different states and circumstances of nouns, there is something required to supply that office. The Latins have no articles; but the

Greeks, and most of the modern languages, have had recourse to them, for fixing and ascertaining the vague signification of common and appellative names. The Greeks have their *ὁ*, the Italians their *il*, *lo*, and *la*; the French their *le*, *la*, and *les*; the Germans their *der*, *das*, *dat*. The English also have two articles, *a* and *the*, which being prefixed to substantives, apply their general signification to some particular things. Some grammarians make the article a distinct part of speech; others will have it a pronoun, and others a noun adjective. See GRAMMAR.

ARTIFICER, a person who works in iron, brass, wood, &c. such as smiths, brasiers, carpenters, &c. The Roman artificers had their peculiar temples, where they assembled and chose their own patron to defend their causes; and they were exempted from all personal services. Taruntinus Paternus reckons 32 species of artificers, and Constantine 35, who enjoyed this privilege. The artificers were incorporated into divers colleges or companies, each of which had their tutelar gods, to whom they offered their worship. Several of these, when they quitted their profession, hung up their tools, a votive offering to their gods. Artificers were held a degree below merchants and *argentarii* or money-changers, and their employment more sordid. Some deny that in the earliest ages of the Roman state artificers were ranked in the number of citizens; others, who assert their citizenship, allow that they were held in contempt, as being unfit for war, and so poor that they could scarcely pay any taxes; for which reason they were not entered among the citizens in the censor's books; the design of the census being only to see what number of persons were yearly fit to bear arms and to pay taxes towards the support of the state. It may be added, that much of the artificers' business was done by slaves and foreigners, who left little for the Romans to mind but their husbandry and war.

ARTIFICIAL, in a general sense, denotes something made, fashioned, or produced by art, in contradistinction from the production of nature.

ARTIFICIAL *Fire-works*. See PYROTECHNY.

ARTIFICIAL *Magnets*. See MAGNETS.

ARTILLERY.

THE discovery of gunpowder by Roger Bacon in the thirteenth century, and of its application to military purposes by Schwartz in the fourteenth, caused a complete revolution in this branch of the art of war. The term *artillery*, previous to this discovery, denoted, in a general sense, all kinds of missiles, and the machines used in propelling them. Thus the artillery of the ancients consisted of the catapulta and balista, of darts, arrows, and other purely mechanical contrivances; while, at a later period, the Franks and their contemporaries used a species of small hatchet as a missile, discharging it at their enemies much in the same manner as the North American Indians do their tomahawks in the present day. However, the signification of the term changing with the advancement of science, we understand by it, in modern phraseology, guns, howitzers, and mortars, with their carriages, beds, ammunition, and apparatus of all kinds, and the troops specially appointed for their management.

In the rapid growth of scientific improvement which, during the last thirty-five years, has extended through every branch of our military establishment, there is nothing more remarkable or more honourable to our national ingenuity and energy than the changes which have been wrought in the organization of the ordnance service.

These changes are such as to render the British artillery, from having been among the worst in Europe, absolutely the very finest and best—an example for the envy of the military powers of the Continent, and a model for the avowed imitation of even that nation which has heretofore been held to excel all others in the qualities of martial science. It has hitherto been admitted by universal consent, that, of all the people of Europe, the French have habitually, in their national character, shown most original genius and aptitude for military affairs; and it is therefore not a little gratifying to the British artillerist to observe these acknowledged masters of the art of war—these boasted instructors of our earlier years—surpassed in their own favourite vocation, and reduced to become in their turn the pupils and imitators of our military knowledge and invention.

This practical homage on the part of the French to the decided superiority of our artillery is a circumstance publicly and candidly admitted by some at least of their own writers. A memoir by the chef-de-bataillon Parizot, a skilful officer of the French artillery, details six essential advantages in the British system over that of his countrymen; and Dupin, who quotes this memoir, adds, in a note, the following testimony of a French general officer

Artifice
||
Artiller.

Artillery. who attended the review of the allied armies of occupation in France in 1818. "J'ai observé, avec beaucoup d'attention, les manœuvres d'artillerie des diverses puissances; j'ai été frappé de la beauté et du luxe de toutes les troupes qui composaient l'armée, de l'ordre et de la précision de leurs mouvemens et de leurs manœuvres; mais les Anglais sont les premiers sous tous les rapports."¹

All the improvements which have raised the British artillery to its present state of perfection are, as we have already said, the work of our own age. At the commencement of our share in the late war in 1793, the various ordnance equipments, as well as the whole composition of this branch of our military service, were of the rudest kind, and on the worst organized and most defective plan. The inefficiency of the whole system, indeed, was palpably betrayed whenever a force was required to take the field. The guns were dispersed among the infantry at the rate of two pieces to a battalion, thereby rendering it impracticable to employ them for their legitimate purpose—the concentrating a powerful fire of numerous guns on any important point. They were also horsed in single team, which needlessly both lengthened the column of march and diminished the power of draught. The drivers were on foot with long whips, as were also the gunners. The ammunition was packed in large rough deal boxes; the waggons which conveyed it were heavy and ill-constructed; and the whole equipment was so cumbersome, that it was impossible for the train to move out of a foot-pace, except for a very short distance; and if increased speed were attempted before the enemy, the men came into action breathless and unable to serve their guns.²

But before the commencement of the peninsular war, that active and able officer the late Major Spearman had entirely re-organized this branch of the service; and it is to him that the country owes the present beautiful system of field artillery. The battalion guns were abolished, and the artillery was brigaded, distinct from the infantry and cavalry with which it served, in divisions of six pieces each; so that the fire of one or more of these powerful batteries could be readily concentrated on any given point. A body of military drivers was organized, while, by an ingenious contrivance of the shafts, the power of using single draught in narrow roads, or when any of the horses were disabled, was retained. The drivers were mounted on the near horses; and the gunners themselves, in the proportion of eight to each piece, were carried on the limbers and ammunition cars. The whole of the equipment was simplified and lightened to such a degree that the batteries could move at a gallop; the ammunition, packed in boxes on the limbers and cars, was always up with the guns; and the officers and men, being all mounted or conveyed on the carriages, were sure of being brought fresh into action. Finally, a system of manœuvres for artillery in the field was introduced, which gave order and precision to their own movements, and established uniformity between them and the troops of other arms.³ The advantages of this system are so ably described in the following observations of a general officer of the French artillery, who was present at the final review of the allied army of occupation in France, that we shall make no apology for introducing them in this place. "La cavalerie, soutenue par des masses d'infanterie, étant sur deux lignes, dans la plaine entre La Selle et l'Ecaillon, on vit à la fois se détacher des différens corps, plus de cent bouches à feu d'artillerie à pied et à cheval; et

se porter, avec la même vitesse, à cent toises en avant de la première ligne de cavalerie. On commença l'affaire par une cannonade, qui ressemblait à un feu de file. Les mouvemens des batteries et les manœuvres des bouches à feu s'exécutent avec beaucoup d'ordre et de précision. La facilité avec laquelle on met et ôte l'avant-train n'a pas échappé aux officiers d'artillerie. Il est survenu un accident à une batterie à pied qui arrivait au galop par un chemin très-escarpé. Ayant rencontré une calèche qui fermait le passage, elle n'hésita pas, dans la crainte d'un retard, à se précipiter dans le champ à gauche. Une seule pièce fut renversée, avec les cannoniers, dont un fut blessé. Elle fut relevée en un instant, et rejoignit sa batterie. Il y eut successivement deux charges de cavalerie par les deux lignes, qui, repoussées, vinrent se rallier l'une derrière l'autre. On vit les cannoniers, emmenant les avant-trains, abandonner les pièces, et revenir aussitôt après la charge, recommencer le feu. Le passage de l'Ecaillon, défendu par l'armée ennemie qui occupait les villages, les ponts, et tous les points importants de la position, donna lieu aux dispositions et aux manœuvres que nécessite une opération de cette importance. Le passage forcé, l'armée ennemie tournée par sa gauche, pressée par les alliés, fit sa retraite, défendant le terrain et les villages, pied à pied, jusque sur les hauteurs du camp de Famars. L'artillerie a suivi les mouvemens des divisions, dans la vallée difficile de l'Ecaillon, et dans la plaine au delà (malgré les obstacles) jusqu'au pied des hauteurs de Famars, arrivant sur le terrain en même temps que les troupes; cette position est couverte par un ravin profond et difficile, qu'elle a franchi comme la cavalerie. Quelques voitures ont versé, mais ont été promptement relevées. Notre artillerie n'aurait surmonté cet obstacle qu'avec beaucoup de temps et de travail."⁴

Field Artillery.

FIELD ARTILLERY.

When an army is to take the field, several considerations must be attended to in apportioning the number and calibre of the batteries to accompany it; as the face, features, and general nature, mountainous or otherwise, of the country which is to form the theatre of war,—the state of its roads, and the resources which it can supply for the means of transport,—the force and description of troops composing the army,—the nature of the war, whether offensive or defensive,—and, lastly, the intended plan of operations.⁵

In carrying on offensive operations in a champaign country, with good roads and facility of transport, the artillery should consist of 9-pounder batteries, to which a few 18 or 12-pounders should be added, to form on occasion batteries of position. There should likewise be one or more batteries of a lighter calibre, to accompany any corps of the army that may be destined by rapid marches to intercept the enemy's convoys or detachments.⁶ In mountainous or deep hilly countries, the artillery should not be composed of heavier ordnance than the 6-pounder battery; but an exact topographical acquaintance with the nature of the country is absolutely necessary, and indeed affords the only satisfactory guide for judging of the most appropriate calibres to be employed. When an army is to remain on the defensive in a country where the roads are only tolerable, and the probability of being obliged to undertake long and rapid marches is not great, the artillery should be composed of a heavier description of batteries

Field
Artillery.

than would be proper to accompany an army acting offensively in the same country. But if this defensive system be carried on in a strong country, where the means of transport are attended with difficulty, and long and rapid marches may become indispensably necessary, the batteries must be so constituted as to adapt them to these se-

veral circumstances, otherwise the artillery will retard the army in its operations, instead of contributing to the attainment of the object in view.¹

The annexed table exhibits the composition of each kind of field battery, and the proportion of ammunition and laboratory stores carried with each piece of ordnance.

Nature of Battery, Ammunition, and Laboratory Stores.	12-Pounders.	9-Pounders.	6-Pounders, Heavy.	6-Pounders, Light.	3-Pounders, Heavy.	24-Pounders, Howitzers.	12-Pounders, Howitzers.	Ammunition Cars.	Store Carts.	Store Waggon.	Forge Waggon.	Spare Carriages.

The flannel cartridges and small stores are distributed in the several boxes in equal proportion with the other ammunition, according to circumstances.

The following historical examples of the relative proportions of artillery acting with various armies in different countries during the late war, may, with the assistance of good topographical maps, enable an officer to form a tolerably accurate judgment on this important branch of military study.

The Austrian army, under the command of the archduke Charles in the campaign of Aspergne, Essling, and Wagram, consisted of about 75,000 men, to whom were attached 18 batteries of brigade, 13 of position, and 11 of horse-artillery; being in the proportion of one piece of ordnance to 260 men nearly.

The allied British and Portuguese army in the field in Spain, May 1813, consisted of 65,000 men and 102 pieces of artillery, including the reserve; being in the proportion of one piece of ordnance to 622 men nearly.

The grand French army under Napoleon, for the invasion of Russia, not including the Austrian contingent, consisted of 400,000 infantry, 60,000 cavalry, and 1200 pieces of artillery; being one piece of ordnance to 383 men.

The French armies united on the Tormes in December 1812 amounted to 80,000 men and 200 pieces of artillery, being in the proportion of one gun to 400 men.

Field
Artillery.

Napoleon in 1813 had 1400 pieces of artillery to 300,000 men, or one gun to 200 nearly. In 1815 his army consisted, as nearly as can be ascertained, by a comparison of several accounts of the campaign, of 130,000 infantry, 20,000 cavalry, and 300 pieces of artillery; being one piece of ordnance to 500 men.

The Prussian contingent of the grand French army for the invasion of Russia, under the command of General D'York, consisted of 20,000 men and 60 pieces of artillery; being in the proportion of one piece of ordnance to 333 men nearly.

Marshal Breesford, at the battle of Albuera, had 29,000 men and 32 pieces of artillery, or one gun to 900 men. His opponent Marshal Soult, in the same action, had 23,000 men and 40 pieces of artillery, or one gun to 575 men.

General L'Espinasse, who commanded the artillery of Buonaparte in Italy, supposes a division of an army to consist of 12,000 men, including a regiment of dragoons and another of hussars, to which he allots three batteries of horse and three of field artillery, each consisting of six pieces of ordnance. A battery of horse and another of field artillery are at all times to be up with the army; two batteries, similarly armed with the two in activity, are to remain with the park; and the remaining two, also appointed in like manner, should be in dépôt in rear of the army. These proportions of artillery to infantry, L'Espinasse states, are precisely those adopted with the approbation of Buonaparte in the Italian campaigns.¹

Positions and Movements of Field Artillery.

The commanding officer of artillery, in order that he may choose proper positions for his field batteries, should be made acquainted with the effect intended to be produced, with the troops that are to be supported, and with the points to be attacked, that he may place his artillery so as to support, but not incommode the infantry, nor take up such situations with his guns as would be more advantageously occupied by the line; that he may not place his batteries too soon, nor in exposed situations; that he may cover his fronts and flanks by taking advantage of the ground; and that he may not venture too far out of the protection of the army, unless some very decided effect is to be obtained by so doing.

In a defensive position the guns of the largest calibre should be posted on those points from whence the enemy can be discovered at the greatest distance, and from whence may be seen the whole extent of his front. In an offensive position, the weakest points of the line, and those most distant from the enemy, must be strengthened by the largest calibres. Those heights on which the army, in advancing, may rest its flanks, must be secured by them, as also those from which the enemy may be fired upon obliquely.

Artillery should never be placed in such a situation that it can be taken by any enemy's battery obliquely, in flank, or in reverse, unless a position under these circumstances offers every prospect of producing a most decisive effect before the guns can be destroyed, or placed *hors de combat*. The most elevated positions are not the best for artillery; the greatest effects may be produced from a height of from 30 to 40 yards at the distance of 600, and from about 16 yards high at 200 yards distant. Those positions which are not likely to be shifted, but from whence an effect may be produced during the whole of an action, are to be preferred, and in such positions breast-works of two or three feet high should be thrown up to cover the carriages.

Field
Artillery.

The guns must be so placed as to produce a cross-fire upon the enemy's position, and upon the ground over which he must pass to attack you. It may sometimes be necessary, in order to concentrate a cross-fire on one particular point, to subdivide your batteries. Thus, his fire may be attracted to different objects whilst your own is directed to a focus, which may be the *débouché* of the enemy, the head of his advancing columns, or the ground in front of the weakest point in your own line. If the enemy's position is to be attacked, your fire must become direct in proportion as the troops advance, otherwise it will impede them; and when you can no longer fire on the point attacked, the guns must be directed on the collateral points.

The guns should be placed as much as possible under cover. This is easily done upon heights, by keeping them so far back as that only the muzzles may be perceived over them. With proper attention, many situations may be found of which advantage may be taken for this purpose, such as banks, ditches, &c. everywhere to be met with. If an enemy's attack is expected, the guns must be posted so as to cannonade him with effect when he advances within 800 paces, and particularly in situations in which his march may be retarded by ditches, defiles, or other natural obstacles.

The position from whence the enemy is to be cannonaded should be kept concealed from him till the moment the batteries are to open. To effect this, the guns may until that time be placed in any other situation. Should there be any small elevations of earth in front of a defile through which the enemy may advance and be cannonaded, the guns must be kept under cover of them until he comes out and begins to form. The guns may also be masked by being covered by troops, particularly cavalry, until the enemy is within the range of case-shot. The covering party must then open right and left, and a brisk fire be kept up.

Artillery should very rarely be placed in front of a line of infantry, or distributed by batteries in the intervals. When the line is of great extent, it may become necessary to place a strong battery in the centre. This should be composed of the guns of the heaviest calibre; and it should be posted in the interval between the right and left wings of the army, by which means a double object is not offered to the enemy's fire. In general, an army in order of battle may be considered as a front of fortification, the infantry forming the curtain, and the lateral batteries the bastions, under the fire of which the troops may manœuvre freely, and advance with confidence to attack the enemy.

The two following examples will serve to illustrate the preceding remarks:—

Battle of Castiglione, 5th August 1796.—The following diagram shows the disposition of the French under Buonaparte, and the imperialists under Wurmser, in this battle:

A B the French army, G H the imperial army, A C a battery of 12 pieces of foot artillery, sustaining the left of the French on the heights in advance of Castiglione; B D

¹ *Essai sur l'Artillerie, par le Général L'Espinasse.*

Siege
Artillery.

a battery of 20 pieces of light artillery appuying on the right, which extended into the plain. The line of infantry A B being taken for the curtain, the batteries A C and B D may be considered as representing the faces of two bastions, thus forming a complete front, and crossing their fire before the curtain. The troops are consequently covered from attack, and the enemy fired upon obliquely. Wurmser having prolonged his front from G to I with the intention of outflanking the French, General L'Espinasse took some of the guns from C A, and placed them on the other face C K, until others could be drawn from the park for that purpose, thus forming a new battery destined to follow the enemy's movements. Another battery was likewise formed on the right, from D to E, in case Wurmser had prolonged his left from H to F.

Battle of Talavera, 27th and 28th July 1809.—At the commencement of the battle the British artillery were stationed, by batteries of six guns each, with the divisions of the army to which they were respectively attached; a temporary redoubt, unfinished, was thrown up at F, in which a battery of 3-pounders was posted; on the hill, at A, the most commanding point of the position, two batteries were posted, one of heavy 6-pounders, the other of light sixes, to which two Spanish guns were afterwards added.

The French had a battery of 14 guns at K, the centre of their position, also one at each of the flanks G and H, independently of others which were brought up during the action. On the second day, when the columns at M advanced, supported by artillery, to attack the British right, which rested on the unfinished redoubt, the three batteries E E E were formed on the oblique line L E, and thus took the advancing columns in flank, whilst the redoubt kept up a direct fire in their front.

It must here be observed, that whenever an oblique line is formed by artillery, as from L to E, it must be directed without the extremity of the enemy's flank, otherwise the guns will be exposed to his enfilading fire.

SIEGE ARTILLERY.

The first duty of the commanding officer of artillery, when it is intended to besiege a fortress, is to prepare an estimate of the quantity of ordnance and ammunition required for its reduction. To enable him to make this estimate with accuracy and precision, he should be master of certain data; that is to say, the commander of the forces, or general charged with the direction of the siege, should communicate to him a plan of the fortifications and environs of the place, accompanied by such profiles and remarks as may enable him, in conjunction with the commanding engineer, to ascertain which front or fronts are most assailable, with the advantages and disadvantages attending each attack, as well with respect to the works of the place, as to the nature of the soil where the trenches must be opened, and the several heights and hollows in the vicinity.¹ He should also, if possible, be informed as to whether the place be amply supplied

with artillery, ammunition, &c.; if the garrison be sufficiently numerous, and whether composed of veteran troops or raw levies; if the governor be in high estimation for his military talents; if the town be populous, and the inhabitants well affected to the garrison.² It will thus be easy to form a tolerably accurate opinion of the means of defence, and the resistance to be expected; for it is not to be presumed that any government would shut up a brave and numerous force in an ill-fortified and badly provisioned place, at the risk of seeing such a garrison sacrificed after a short resistance.

But should it be impossible to procure information on these several points beforehand, particularly as to the strength of the garrison, the requisite proportion of ordnance and ammunition must be regulated on the general principles of attack. The officer intrusted to prepare the estimate must, therefore, endeavour to ascertain, according to the fundamental maxim of all besiegers, against which front or fronts the attack can be made with the least exposure and greatest expedition. He should examine whether the siege can be most advantageously carried on by regular approaches; by taking advantage of any defect in the situation which may enable him to break ground close to the works to be breached; or by battering them from a distance. By the aid of this investigation, and the following general principles, the quantity of ordnance and ammunition required for the siege of a place may be ascertained with the greatest accuracy.

General Principles for the Attack of Fortified Places.

1. The number of batteries to be opened against the defences must depend upon the extent of the works to be embraced by the attack, *i. e.* there must be a battery to enfilade every face that can in any way annoy or retard the besiegers in their approaches.

2. The length of the epaulement of these batteries need not exceed the breadth of the terreplein of the works to be enfiladed, unless circumstances should render it necessary to place some of the guns in a situation to take the work in reverse. Each battery will only contain, therefore, five, or at most eight guns, to enfilade the face of the principal work; to which must be added two others to enfilade the branches of the opposite covered-way.

3. The situation of the breaching batteries must be determined, as, in a regular attack, they sometimes interfere with the fire of the first or enfilading batteries. Should this be the case, the same artillery must be transferred from one battery to the other.

4. The supply of ordnance must be sufficiently liberal to enable the besiegers to keep up a fire constantly superior to that of the place. This supply is determined by the extent of the fortifications of the place; one piece of ordnance must be allowed for every twelve or fifteen feet.

5. As the *ricochet* firing may be interrupted while the sappers are completing the third parallel, a supply of royal and cohorn mortars must be provided to harass the garrison from the second parallel, or demi-places of arms, during its cessation.³

Having thus ascertained the number of guns required, the following will be their calibres, and the proportions which the remaining ordnance should bear to them.

Guns—of the whole number required—suppose 60.

24-pounders..... $\frac{2}{3}$ or 40

12-pounders..... $\frac{1}{3}$ or 20

Howitzers—one for every four guns—in this case 15.

10-inch..... $\frac{1}{2}$ or 5

8-inch..... $\frac{2}{3}$ or 10

Siege
Artillery.¹ *Traité Élémentaire d'Artillerie.*² *British Gunner.*³ *Ibid.*

Siege
Artillery.

Mortars—in the proportion of one-twelfth more than the number of guns—in this case 65.

10-inch.....	$\frac{2}{3}$ or 10
8-inch.....	$\frac{2}{3}$ or 15
Royal.....	$\frac{4}{3}$ or 20
Cœhorn.....	$\frac{4}{3}$ or 20

In the above proportion of ordnance, it must be observed that the long 12-pounder is proposed instead of the 18-pounder formerly employed, as a gun of this description is conceived to be sufficiently powerful for annoyance and direct fire, to dismount the enemy's artillery, as well as for firing *en ricochet*. The diminished weight of ammunition attendant on the employment of the smaller calibre is an important advantage; but it is an arrangement which can only be admitted in cases where an adequate number of 24-pounders are provided. In all smaller equipments it would, therefore, be better that all the guns should be of the heavy calibre.¹

The proportion of small mortars should in no case be less than that of the heavy mortars and howitzers, and this proportion ought to be increased in all equipments of less than thirty pieces of ordnance: indeed, when sent at all, there should be at least twelve of them, to insure the necessary effect: in many cases a far greater number than is here proposed could be advantageously used, but this must of course depend on the nature of the service on which they are likely to be employed. The royal and cœhorn mortars have in the present instance been taken in equal proportions, and it would be advisable to adhere to this arrangement in all the larger equipments, particularly when their calibres correspond with those of the guns; but in small equipments it would be more convenient to confine the arrangement to one calibre, in which case the royal mortar is the preferable, as it possesses the power of being used at a greater distance than the cœhorn. But it must at the same time be observed, that the latter, from its lightness and the small weight of its ammunition, is a more desirable implement for the more advanced parts of the attack.

The quantity and relative calibres of the ordnance being determined, the following will be the proportion and nature of ammunition.

Gun ammunition.—Round shot,

24-pounder.....	1000 rounds per gun.
12-pounder.....	1200 rounds per gun.
Tier shot.....	50 rounds per gun.
Spherical case.....	100 rounds per gun.

Howitzer ammunition.—Shells,

10-inch.....	600 rounds per howitzer.
8-inch.....	300 rounds per howitzer.
Spherical case,	
8-inch.....	300 rounds per howitzer.
Carcasses.....	10 rounds per howitzer.

Valenciennes composition,
10-inch.....100 proportions per howitzer.

Mortar ammunition.—Shells,

10-inch.....	600 per mortar.
8-inch.....	600 per mortar.

Pound shot,

10-inch...50 rounds of 100 shot each per mortar.

Carcasses,

10-inch.....	10 per mortar.
8-inch.....	10 per mortar.

Valenciennes composition,

10-inch.....100 proportions per mortar.

In the above proportion of ammunition there is an increase of two hundred rounds in favour of the 12-pound-

ders, as the facility of working these guns will, at an easy rate, afford the means of firing more rapidly than from 24-pounders. The proportion of one half common shells and one half spherical case should always be adhered to for the 8-inch howitzers.

Arrangement of Artillery at a Siege.

The first disposition of the artillery at a siege is to the different batteries raised near the first parallel. The object of the besieger in the construction of these batteries is, by a direct and enfilade fire, to dismount the artillery on the front attacked, destroy the embrasures, and harass the garrison in the several points of defence, so that they may be compelled to abandon them, or at least slacken their fire, and thereby enable the besieger to carry forward his approaches with greater expedition and less danger than he otherwise could do.² If these first batteries be favourably situated, the artillery may be continued in them during the whole of the siege, or until the besiegers arrive on the crest of the glacis. The garrison must be perpetually harassed along the whole front attacked, with shot and shells fired *en ricochet*. The batteries for this purpose are erected on the prolongations of the works to be enfiladed, from whence the defenders of the prolonged faces may be fired upon with great precision and effect.³ It, however, frequently happens, from local and other circumstances, that the besiegers cannot avail themselves of the most advantageous situations for their first batteries. There are four situations from which the defences of a place may be destroyed, though not from all of them with equal facility. The best positions for the first batteries are those before described as perpendicular to the prolongations of the faces of the works to be enfiladed. If these positions cannot be attained, the next that present themselves are on those sides of the prolongations which take the faces in reverse, and under as small angles as possible. If the ground or other circumstances will not admit of either of these situations being occupied by enfilading batteries, the battery to destroy the fire of the face must be without its prolongation, so as to fire obliquely upon the outside of it: the fourth position in point of advantage is directly parallel to the face. The guns must fire *en ricochet* from the first two positions, and from the last two with full charges.

The second batteries are generally placed on the glacis, within fifteen or eighteen feet of its crest; but if the foot of the revetment cannot be seen from this situation, they must be placed in the covered-way, within fifteen feet of the counterscarp.⁴ The object of these second batteries being to effect practicable breaches in the works, they should be combined, two and two together, so that while one batters in breach, the other may play upon its defences. The breaching batteries shall commence by marking out as nearly as possible, by their fire, the extent of the breach intended to be made; first, by striking out a horizontal line as near as possible to the bottom of the revetment; and next, by aiming at two others, perpendicular to and at the extremities of this first line. Then, by continuing to deepen these three cuts, and occasionally firing salvoes at the part to be brought down, the wall will in time give way in a mass. The guns must begin by firing as low as possible in the commencement of the operation, afterwards somewhat higher in the same manner as before, and so continue advancing gradually upwards till the breach is effected; for, should they fire too high at first, the rubbish would cover the lower part of the wall, retard the operation, and tend to render the

¹ British Gunner.

² Essai Générale de Fortification.

³ British Gunner.

⁴ Traite d'Artillerie, par D'Antoni; British Gunner.

breach impracticable. When the second batteries are placed on the glacis, or in the covered-way, they must be sunk to such a depth that the terreplein of the one, or surface of the other, may coincide with the soles of their embrasures. They are in fact but an enlargement of the sap run for the lodgement on the glacis, or in the covered-way, and should contain at least four guns each. If the space between the traverses will not admit of this number at the usual distances, the guns must be closed from twelve to fifteen feet of each other.

The mortars are generally arranged at first in battery, adjoining the first gun batteries, or upon the prolongations of the capitals of the works, in which situations they are certainly least exposed; and upon the establishment of the half parallels the howitzers are placed in battery, in their extremities, to enfilade the branches of the covered-way. These batteries are in the most advantageous situations, if, while the one bombards the work that the besieger intends to assault, and prevents the garrison from throwing up intrenchments within it, or at least retards their construction, the other directs its fire against the defences of the breach, so that the garrison may, from the continual shower of shells, &c. be compelled to abandon them, or, if they persist in remaining, be exposed to great loss. The small mortars are arranged in the third parallel, to annoy the besieged in the places of arms.

In the establishment of all these batteries, the great object is to make such an arrangement of them, that they may not mask the fire of each other more than cannot be avoided, and particularly that of the first or *ricochet* batteries. The aggravation of this inconvenience may very well be prevented till the establishment of the attack on the crest of the glacis, when it becomes in some degree unavoidable: however, even the operations of the glacis may be so arranged as not to mask the fire of the *ricochet* batteries, until the breaching batteries are in a state of great forwardness.

GARRISON ARTILLERY.

The proportion of ordnance, ammunition, and stores required for the defence of a fortified place depends not only on the particular situation of each individual fortress, and its relations with the surrounding country; the system according to which it is fortified, and the species of attack it may be possible to open against it; but likewise on innumerable minor circumstances, each of which may exert an important influence on the defence. If, for example, one or more of the fronts of a place be covered by an inundation, a marsh, or by any other impassable obstacle, it will manifestly require a much smaller proportion of artillery for its defence than if it were equally accessible on every front. On the contrary, a maritime fortress, which is susceptible of attack both by sea and land, will require a larger proportion of ordnance supplies than if it were assailable from only one of these points.¹

It will be seen, therefore, from the above remarks and examples, how impossible it is to lay down any general rules upon this important subject. The only satisfactory guide which an officer charged with the nice and responsible trust of arming a fortified place can with security follow, is to examine attentively all parts of the works and of the surrounding country, and then to weigh every other circumstance that can in any way influence the defence. He should consider which of its fronts are most vulnerable, and what measures are best adapted for their security.

To effect this with accuracy and expedition, he should, after a few days passed in reconnoitring and studying his position, devote his attention to the preparation of a sketch and profiles of the works and neighbouring country, as far at least as a mile in every direction, and upon a scale adapted to the features of the ground.

With this map and profiles before him, he should recur to those fundamental principles upon which every good attack and defence are based. He should not only be thoroughly acquainted with his own particular branch of the service in all its details, but capable of judging to the fullest extent of all operations in which the other troops of the garrison can bear their part; so that every supply may be adequate to its particular purpose, without deficiency on the one hand or superfluity on the other. Thus two extremes, equally prejudicial, will be avoided; the one, of making a provision insufficient for the defence which the fortress is capable of sustaining; the other, of providing such a quantity of supplies, that, on its capitulation, which, according to the natural order of things, must sooner or later happen, if it be not relieved, a complete arsenal would fall into the enemy's hands.²

These observations being held in mind, the following general maxims will be found of essential assistance.

General Maxims for arming Fortified Places.

1. The proportion of ordnance, ammunition, and stores should never exceed the quantity absolutely necessary to a brave and resolute defence.
2. Those fronts which are considered susceptible of attack should be completely armed, and the remaining fronts only in part.
3. These should be, for each of the faces of the bastions of such fronts as are deemed liable to attack, five or six pieces of ordnance; for each of the flanks of these bastions four pieces; and for the faces of the ravelin from five to seven pieces of ordnance. When these are lunettes, four pieces should be reckoned for each, and from two to three for each of the places of arms of the covered-way. Supposing, therefore, one front to be completely armed, the following proportion of ordnance will be required.

The faces of the two bastions.....	from 10 to 12
two interior flanks	from 6 to 8
faces of the ravelin.....	from 5 to 7
five places of arms.....	from 10 to 15
making a total for one front of from 33 to 42 pieces of ordnance.	

4. In case of the place being liable to attack on two consecutive fronts, the above proportion should be augmented one half; and if on two detached fronts, it should be doubled. The remaining fronts should each be provided with such a proportion of their full armaments as will secure them from insult. It will appear from the above maxims, which are deduced from the best authorities on the subject, that a hexagon, having only one front exposed to attack, requires an armament of from 58 to 68 pieces of ordnance for its defence; and that for more extensive places, from six to eight, or at most ten pieces of ordnance, should be added for each additional front.³

The next point to be considered is the proportion which the several kinds of ordnance, and their relative calibres, should bear to each other; and here it must be remembered that the higher rates are not the only descriptions capable of being employed to advantage in the defence of a place. There are many cases in which medium guns can oppose equal resistance with the heavier calibres, and

¹ British Gunner.² Manuel de l'Artilleur; Traité d'Artillerie, par D'Antoni.³ Traité Élémentaire d'Artillerie.

Garrison
Artillery.

they possess the very important advantage of affording greater facility in manœuvring and transporting them from one situation to another; an operation of considerable difficulty with the higher natures of ordnance at all times, but particularly during a siege. They also consume less ammunition, and enable the besieged to keep up a more determined and incessant fire.¹

The following are the proportions of the several kinds and calibres usually adhered to in ordinary cases.

Guns—in the proportion of two thirds of the whole armament—suppose 60.

24-pounders.....	$\frac{1}{10}$ or 6
18-pounders.....	$\frac{2}{10}$ or 12
12-pounders.....	$\frac{3}{10}$ or 18
9-pounders.....	$\frac{4}{10}$ or 24
Howitzers—one for every five guns—in this case 14.	
10-inch.....	$\frac{1}{2}$ or 7
8-inch.....	$\frac{1}{2}$ or 7

Mortars—in about the same proportion as the howitzers—in this case 16.

10-inch.....	$\frac{1}{2}$ or 8
8-inch.....	$\frac{1}{2}$ or 8

The above distribution of guns, howitzers, and mortars, applies equally to all armaments of not less than sixty pieces of ordnance; and such an armament should therefore consist of forty guns, eight howitzers, and twelve mortars. The proportions of the several calibres of each kind, except those for the guns, are calculated on a basis of not less than ninety pieces of ordnance; and in all smaller armaments it would be advisable to confine the arrangement to two calibres of each kind only.

The following will be the proportion and nature of ammunition for each species of ordnance.

Gun ammunition.—Round shot,

24-pounder.....	600 rounds per gun.
18-pounder.....	760 rounds per gun.
12-pounder.....	800 rounds per gun.
9-pounder.....	1000 rounds per gun.

Case shot,

24-pounder.....	40 rounds per gun.
18-pounder.....	50 rounds per gun.
12-pounder.....	80 rounds per gun.
9-pounder.....	100 rounds per gun.

Spherical case,

24-pounder.....	50 rounds per gun.
18-pounder.....	80 rounds per gun.
12-pounder.....	100 rounds per gun.
9-pounder.....	150 rounds per gun.

Howitzer ammunition.—Shells,

10-inch.....	400 rounds per howitzer.
8-inch.....	600 rounds per howitzer.

Case shot,

10-inch.....	100 rounds per howitzer.
8-inch.....	250 rounds per howitzer.

Spherical case,

8-inch.....	500 rounds per howitzer.
-------------	--------------------------

Light balls and carcasses,

8-inch.....	20 rounds of each per howitzer.
-------------	---------------------------------

Mortar ammunition.—Shells,

10-inch.....	500 rounds per mortar.
8-inch.....	650 rounds per mortar.

Pound shot,

10-inch.....	500 rounds per mortar.
8-inch.....	600 rounds per mortar.

Each round of pound shot consists of 100 shot for the 10-inch, and of 80 for the 8-inch mortar.

Light balls..... 15 per mortar.

The above proportion of ordnance and ammunition for

the defence of a fortified place is exclusive of one or more field batteries, which every place should contain, according to its extent, and which should be provided with a double proportion of ammunition. (See the preceding section on FIELD ARTILLERY.)

This estimate and arrangement is founded upon the supposition that the place is unprovided with casemated batteries, the armament for which must of course form a separate estimate, calculated, however, upon the same principles as the above.

Arrangement of the Artillery during a Siege.

The instant it is ascertained that the enemy's troops are in motion towards the place,—presuming that it is amply supplied with provisions, ammunition, and stores, and that every precaution has been taken to collect from the vicinity what might fall into the enemy's hands,—the barbette batteries must be established in the flanked angles of the bastions and ravelins, and a proportion of the light guns and howitzers must be placed in the outworks and covered-way. Should the body of the place have cavaliers, the heaviest guns should be mounted on them. The following arrangement is usually made for the reception of the investing corps, when it is not known from what point they may advance to commence operations.

There should be three guns mounted on the barbette of each bastion,—one 24 and two 18-pounders, and three 9-pounders on the barbette of each of the ravelins. In the salient places of arms of the bastions one 24-pounder howitzer, and in those of the ravelins two 6-pounders. The heavy mortars should be placed one in each bastion, and the remainder of the ordnance in reserve behind the curtains, ready to move on whichever side it may be required.

By this arrangement the whole of the barbette guns, and of the guns and howitzers in the outworks and covered-way, will be in readiness to act in any direction, till it is known on which side the enemy has determined to direct his attack, and, with the addition of the reserve, will enable the besieged to open a fire of thirty-five pieces of ordnance on the enemy the very first night he begins to work upon the trenches. In the first moments of the investment, however, the artillery of the place should not endeavour, by a useless expenditure of ammunition, to disturb the besiegers in their operations: it is only when they are making permanent dispositions for their establishment that the fire of the place should be opened upon them. It is nevertheless necessary that some guns should be loaded with reduced charges, to protect the retreat of the advanced posts, and mislead the enemy as to their range. This is also the moment, if the garrison be numerous, and composed of good troops, to annoy the besiegers, by sorties on different points of the line of contravallation, and to retard the works necessary for establishing their communications: care must, however, be taken not to purchase this advantage by a loss of men and artillery, which would cripple the means of defence.

The day succeeding the night on which the trenches are opened, and the front of attack determined, a new disposition of the artillery of the place must be made as follows:—

The 24 and 18-pounders must be removed to the front attacked, and the other batteries, if necessary, supplied with 12-pounders. The barbettes of the bastions on this front must have each five guns, three 24 and two 18-pounders, and the remaining 18-pounders arranged behind the curtains,—two towards each of the extremities

Garrison
Artillery.

¹ British Gunner.

Exercises. of the front curtain, and two at the farthest extremity of each of the collateral curtains. The howitzers in reserve should be placed, two in each of the salient angles of the covered-way of the bastions of this front, and two in each of those of the collateral bastions, which, with those already there, must fire *en ricochet* down the prolongations of the capitals. There should also be three 6-pounders in the salient place of arms of the ravelin of the front attacked, and three in each of those of the two collateral ravelins; these guns should fire over the palisading; and, lastly, there should be five 9-pounders on the barbette of the front ravelin. This arrangement will bring fifty-two guns and howitzers and four mortars to fire on the approaches, after the first night. This, with a few variations, will be the disposition of the artillery of the place till the besiegers' first batteries are ready to open. The instant they begin to work upon these batteries, the whole fire of the place must be concentrated on them, and the mortars which had previously fired at low angles must now fire with greater elevation, but at all times sparingly.

As soon as the enemy's batteries are fairly established, the guns *en barbette* must be covered by merlons, and the embrasures occasionally masked. While this work is carrying on, the situations of the guns should be changed, and new directions given to them; as by frequently practising this manœuvre, the enemy will also be obliged to change his dispositions of attack, and time will thereby be gained by the besieged. As the enemy approaches towards the second parallel, the fire of the place must be spread over all parts of his line of operations; and with a view of contributing to this object, royal and cæhorn mortars should be disposed in the places of arms and branches of the covered-way. When the approaches are carried on from the second parallel, and the enemy is about to establish the demi-places of arms, the fire of the place must be concentrated on the *débouchés* from the parallel, and multiplied with all possible activity.

In proportion as the besieger pushes forward his approaches to the third parallel, the artillery must be withdrawn from the covered-way to the ravelins, or to the ditch, if dry, or to any other favourable situation, and by degrees, as they advance, to the body of the place. During this period of the siege the embrasures must be prepared in the flanks, in the curtain which joins them, and in those parts of the faces of the bastions which command the ditch of the front ravelin. All these embrasures must be ready to open, and the heavy artillery mounted in them, the moment the enemy attempts to form a lodgment on the glacis. We have now arrived at the crisis of the siege, and every effort should be made to take advantage of this favourable moment, when the enemy, by his own works, must mask his former batteries, and before he is able to open his new ones.

EXERCISE OF ARTILLERY.

The several exercises are divided into three classes, as follows:—

1. Exercise of field artillery.
2. Exercise of garrison or siege artillery.
3. Exercise of the various machines employed in the manœuvres of garrison or siege artillery.

1. Exercise of Field Artillery.

The complement of men for the service of each gun or howitzer is, one non-commissioned officer and eight gunners.

Numbering and Telling Off the Detachments.

The several detachments being arranged right in front,

Exercises. are numbered and told off by their respective non-commissioned officers in the following manner:

The non-commissioned officer is invariably No. 1, and is responsible for the proper execution of the duties of the other numbers of his detachment. The right-hand man of the rear rank is named No. 2; his front-rank man No. 3; the second man from the right of the rear rank No. 4; and his front-rank man No. 5; and so on in succession from the right of the rear to the left of the front rank, till the numbering of the whole detachment is completed.

Formation in Order of March, or for Exercise.

When detachments are formed in the order of march, or for the purpose of exercise, the even numbers are almost invariably on the right or off-side of the gun, and the odd numbers on the left or near side.

Positions of the several Numbers in Action.

No. 1 is on the left of the handspike; No. 2 outside the right wheel, in line with the muzzle; No. 3 outside the left wheel, and also in line with the muzzle; No. 4 clear of the right wheel, covering No. 2, and in line with the breech; No. 5 clear of the left wheel, covering No. 3, and also in line with the breech; No. 6 five paces in rear of and covering the left wheel; No. 7 in rear of the limber; No. 8 ten yards in rear of the gun, in line with the heads of the leading horses of the limber; and No. 9 attends the ammunition-wagon.

Duties of the several Numbers.

No. 1 points and commands; No. 2 sponges; No. 3 loads; No. 4 serves the vent and primes; No. 5 fires; No. 6 serves No. 3 with ammunition; No. 7 supplies No. 6 with ammunition, and, when firing shells, fixes the fuses; No. 8 assists No. 7, and occasionally relieves No. 2, or, when attached to 5½ inch or 24-pounder howitzers, provides No. 3 with shells; No. 9 assists in preparing ammunition.

Limbering up, or Retiring from Action.

This manœuvre may be performed, according to circumstances, to the front, rear, right, or left. In limbering up to the front, the limber drives up to the right of the gun. No. 2 instantly passes his sponge over the axle-tree to No. 4, who straps on the sponge head; No. 2 and No. 3 go round to the trail; No. 4 and No. 5 man the wheels, assisted by No. 7 and No. 8 with heavy guns. The right wheel is run back, the left forward, and No. 1 and No. 6 throw the trail round in the opposite direction to that in which the limber drives up. The instant the trail is round, No. 1 unships his handspike, and No. 5 straps it on; No. 2 buckles on the rammer-head of his sponge, and the whole fall in close to the wheels. No. 6, No. 4, and No. 2 on one side, No. 5, No. 3, and No. 1 on the other; No. 7 attends the limber, and No. 8 moves up to his place. On the limber coming up square to the front, No. 1 orders, "halt, limber up," upon which No. 4 and No. 5 man the wheels, No. 2, No. 3, and No. 6, lift the trail and place it on the pintail; No. 1 then puts in the key, and the detachment mount, or fall into the order of march. The duties are precisely the same in limbering up to the rear, right, or left, except that in limbering up to the right or left, the trail and limber both go to the right or left; and in limbering up to the rear, the limber drives up rather to the right of the trail, which is not thrown round, and then reverses to the left.

Unlimbering or coming into Action.

This is precisely the reverse of the preceding manœuvre. No. 1 unkeys the pintail, No. 2 and No. 3 raise the trail,

Exercises. and when it is clear No. 1 gives the word, "Drive on;" upon which the limber goes off to the left about, and the trail is thrown to the right about, the other numbers assisting as they arrive, the same as in limbering up, No. 6 at the trail with heavy guns, and No. 4 and No. 5 at the wheels. As soon as the trail is down, No. 5 unbuckles the handspike, and No. 1 ships it; No. 2 unstraps the rammer-head and goes to his place; No. 4 unstraps the sponge, and passes it over to No. 2. When the limber is sufficiently to the rear, it reverses to its left, and halts ten yards in rear of and covering its gun. The ammunition-waggon also reverses to its left, goes off in front of the limber, and again reversing to its left, halts one horse's length in rear of the gun-limber. No. 1 is responsible for the correct dressing of his gun when it comes into action; and for this purpose, immediately after the trail is in its proper direction he should place himself in line with the axle-tree of the gun upon which the formation is made, and dress his own gun with it. This position will enable him to see, not only that his gun is in its true *alignment*, but also that it is square to the front.

2. Exercise of Garrison or Siege Artillery.

This second branch of the exercises relates to the manner of working and serving guns, howitzers, carronades, and mortars, on batteries. The complement of men for the service of garrison or battery guns is, for the 42-pounder and 32-pounder, one non-commissioned officer and six gunners each; for the 24-pounder, one non-commissioned officer and five gunners; for the 18-pounder, one non-commissioned officer and four gunners; and for the 12-pounder and 9-pounder, one non-commissioned officer and three gunners each. The complement of men, duties, &c. are precisely the same for howitzers and carronades as the above for guns. The 13-inch mortar requires one non-commissioned officer and five gunners; the 10-inch mortar one non-commissioned officer and four gunners; the 8-inch mortar one non-commissioned officer and three gunners; and the royal and cœhorn mortars one non-commissioned officer and two gunners each.

All calculations for the daily service of guns on batteries, whether in garrison or at a siege, should be made in three proportions and at three reliefs.

Numbering, Telling Off the Detachments, and Formation for Exercise.

The same in every respect as for field artillery.

Positions and Duties of the Numbers.

No. 1, directly in rear of the gun, points, commands, and assists to run the gun up; No. 2, on the right of and in line with the muzzle, sponges, runs up, and elevates; No. 3, on the left of the muzzle, and also in line with it, loads, runs up, and elevates; No. 4, on the right of the gun, clear of the track, and in line with the breech, serves the vent, primes, runs up, and traverses; No. 5, in the same relative position on the left of the gun, fires, runs up, and traverses; the remaining numbers on the right and left of the embrasure, with their backs to the merlons. No. 6 serves No. 3 with ammunition, and runs up; No. 7 assists to run up. The whole of the numbers, when not immediately employed in working the gun, should range themselves in order under cover of the parapet.

In serving mortars, No. 1 is directly in rear of the mortar, and points, commands, and serves the vent; No. 2, on the right of and in line with the front of the bed, sponges, runs up, and traverses; No. 3, in the same relative position on the left of the bed, loads, runs up, and traverses; No. 4, on the right of the mortar, covering No. 2, and in line with the vent, runs up, elevates, supplies shells, primes, and tra-

verses; No. 5, in the same relative position on the left of the mortar, runs up, supplies shells, elevates, traverses, and fires; No. 6, at the magazine, serves ammunition. No. 2 puts the shells into the 8-inch royal and cœhorn mortars, and in putting them into the 13 and 10-inch mortars is assisted by No. 3.

3. Exercise of the various Machines employed in the Manœuvres of Heavy Artillery.

The method of numbering, telling off, &c. is the same in every respect for this branch of the exercises as for the two preceding, except that, in the exercise of the devil-carriage, the odd numbers are posted on the right side, and the even numbers on the left.

Exercise of the Triangle Gyn.

The complement of men for a triangle gyn is usually one non-commissioned officer and ten gunners. The following are the duties in working or carrying the gyn:

Left side.

No. 3 carries at the foot of the left cheek, works the left-hand lever, keys and unkeys the left-hand capsquare of the gun-carriage, and assists to run the carriage up or back.

No. 5 carries at the top of the left cheek, works the left centre lever, and assists to run the carriage up or back.

No. 7 carries the levers and handspikes, assists No. 6 in passing the fall round the windlass, and holds on next to him.

No. 9 carries at the top of the pry-pole with the slings, fid, trucks, &c., holds on the fall behind No. 8, and coils it up as it comes off.

No. 11 Assists in carrying the blocks and fall, reeves and unreeves the triple block, assists in slinging the gun, and steadies it at the muzzle.

Right Side.

No. 2 carries at the foot of the right cheek, works the right-hand lever, keys and unkeys the right-hand capsquare of the gun-carriage, and assists to run the carriage up or back.

No. 4 carries at the top of the right cheek, works the right centre lever, and assists to run the carriage up or back.

No. 6 carries the windlass, passes the fall round it, holds on, makes it fast, and eases off and lowers the gun.

No. 8 carries at the foot of the pry-pole with the slings, fid, trucks, &c., and holds on next to No. 7.

No. 10 assists in carrying the blocks and fall, reeves and unreeves the double block, assists in slinging the gun, and steadies it at the cascable.

Exercise of Bell's Gyn.

The complement of men for working this gyn is one non-commissioned officer and six gunners.

Left side.

No. 3 runs the carriage up or back, assists No. 6 in slinging the gun, turns the winch, assisted by No. 5, or makes fast and hauls upon the rope which is passed round the handles of the winch.

No. 5 runs the carriage up or back, and assists No. 3 at the winch.

No. 7 slings and unslings the gun at the chace, assisted by No. 3, and steadies at the muzzle.

Right side.

No. 2 runs the carriage up or back, assists No. 7 in slinging the gun, turns the winch, assisted by No. 4, or holds on upon the rope and makes it fast, the same as No. 3.

No. 4 performs similar duties to No. 5 on his own side.

No. 6 slings and unslings the gun at the first reinforce, assisted by No. 3, places the bed and quoin, and steadies the gun at the cascable.

Exercise of the Sling-cart.

The complement of men for a sling-cart is one non-commissioned officer and six gunners.

Left side.

No. 3 has charge of the left lever, and when necessary assists to sling the gun.

No. 5 assists No. 3 at the lever and skidding, and when the gun is lashed assists in raising the breech.

No. 7 assists No. 3 at the lever, slings and unslings the gun, and lashes it to the pry-pole.

The non-commissioned officer puts in and takes out the pauls, and commands.

Right side.

No. 2 has charge of the right lever, and when necessary assists to skid the gun.

No. 4 in like manner assists No. 2, and when the gun is lashed assists in raising the breech.

No. 6 assists No. 2 at the lever, in slinging and unslinging the gun, and lashing it to the pry-pole.

No. 4 steadies the gun-carriage when raised on its breast transom, and with the long guy-rope lashes its front axle-tree to the devil-carriage.

No. 6 slings the gun, lashes the breech to the perch, assists in limbering up and unlimbering, and slings the gun-carriage.

No. 8 has charge of one of the short guys, assists in unlimbering and limbering up, and in hauling the breech of the gun up to the perch; lashes the hind axle-tree of the gun-carriage to the devil-carriage, and fixes the long guy-rope to the iron eyes at the end of the perch.

No. 10 assists in unlimbering and limbering up, and in hauling the breech of the gun up to the perch; lashes with the short guy-ropes the rear axle-tree of the gun-carriage to the devil-carriage, and fixes the short guy-ropes to the ring under the perch.

No. 5. The duties of No. 5 are in all respects the same as those of No. 4.

No. 7. The duties of No. 7 are the same as those of No. 6, only performed on his own side of the carriage.

No. 9 does the same as No. 8.

No. 11 does the same as No. 10.

Artlen-
burg
||
Arts.

Exercise of the Devil-carriage.

The complement of men for working this carriage is one non-commissioned officer and ten gunners.

Left side.

No. 2 has charge of a drag-rope, assists in hauling the perch up and down, assists No. 3 in bearing the muzzle down, and, when the gun and carriage are lashed on, puts up the skid.

Right side.

No. 3 has charge of a drag-rope, assists in hauling the perch up and down, bears the muzzle of the gun down, and, when the breech is raised, puts the lever into the muzzle.

ARTILLERY Park, the place in the rear of both lines of an army for encamping the artillery, which is drawn up in lines, of which one is formed by the guns; the ammunition-waggons make two or three lines, 60 paces behind the guns, and 30 distant from one another; the pontoons and tumbrils make the last line. The whole is surrounded by a rope, which forms the park; the gunners and matrosses encamp on the flanks; and the bombardiers, pontoon-men, and artificers, in the rear.

ARTILLERY Train, a certain number of pieces of ordnance mounted on carriages, with all their furniture fit for marching.

ARTILLERY Company, a band of infantry, consisting of 600 men, making part of the militia or city guard of London.

ARTIST, in a general sense, a person skilled in some art. Mr Harris defines an artist to be "a person possessing an habitual power of becoming the cause of some effect, according to a system of various and well-approved

precepts." It is generally applied to an individual who practises the liberal arts as a profession.

ARTLENBURG, a bailiwick in the province of Luneburg, in the kingdom of Hanover, extending over 27 square miles, or 17,280 acres, and containing 3020 inhabitants. A town of the same name, with 525 inhabitants, is the capital of the bailiwick. It is on the banks of the Elbe, and enjoys the benefit of a toll over the river.

ARTOTYRITES, a Christian sect in the primitive church, who celebrated the eucharist with bread and cheese, saying that the first oblations of men were not only of the fruits of the earth, but of their flocks. The word is derived from *artos*, bread, and *tyros*, cheese. The Artotyrites admitted women to the priesthood and episcopacy; and Epiphanius tells us it was a common thing to see seven girls at once enter into their church, robed in white and holding a torch in their hand, where they wept and bewailed the wretchedness of human nature and the miseries of this life.

(F. F.)

A R T S.

ART is defined by Lord Bacon as a proper disposal of the things of nature by human thought and experience, so as to answer the several purposes of mankind; in which sense *art* stands opposed to *nature*.

Art is principally used for a system of rules serving to facilitate the performance of certain actions; in which sense it stands opposed to *science*, or a system of speculative principles.

Arts are commonly divided into useful or mechanic, fine or liberal. The former are those wherein the hand and body are more concerned than the mind; of which

kind are most of those which furnish us with the necessities of life, and are popularly known by the name of trades. The latter are such as depend more on the labour of the mind than of the hand; they are the produce of imagination and taste, and their end is pleasure.

USEFUL ARTS.

Some useful arts must be nearly coeval with the human race; for food, clothing, and habitation, even in their original simplicity, require some art. Many other arts are of such antiquity as to place the inventors beyond the

Useful
Arts.

reach of tradition. Several have gradually crept into the world without an inventor. The busy mind, however, accustomed to a beginning in things, cannot rest till it finds or imagines a beginning to every art. The most probable conjectures of this nature the reader may see in the historical introductions to the different articles. Lord Kames, in his *Sketches of the History of Man*, has given some curious illustrations of the progress of the arts.

In all countries where the people are barbarous and illiterate, the progress of arts is extremely slow. It is vouched by an old French poem, that the virtues of the loadstone were known in France before the year 1180. The mariner's compass was exhibited at Venice anno 1260, by Paulus Venetus, as his own invention. John Goya of Amalfi was the first who, many years afterwards, used it in navigation, and also passed for being the inventor. Though it was used in China for navigation long before it was known in Europe, yet to this day it is not so perfect as in Europe. Instead of suspending it in order to make it act freely, it is placed upon a bed of sand, in which position every motion of the ship disturbs its operation. Handmills, termed *querns*, were early used for grinding corn; and when corn came to be raised in greater quantity, horse-mills succeeded. Water-mills for grinding corn are described by Vitruvius. Wind-mills were known in Greece and in Arabia as early as the 7th century, and yet no mention is made of them in Italy till the 14th. That they were not known in England till the reign of Henry VIII. appears from a household book of an earl of Northumberland, contemporary with that king, stating an allowance for three mill-horses, "two to draw in the mill, and one to carry stuff to and from the mill." Water-mills for corn must in England have been of a later date. The ancients had mirror-glasses, and employed glass to imitate crystal vases and goblets; yet they never thought of using it in windows. In the 13th century the Venetians were the only people who had the art of making crystal glass for mirrors. A clock that strikes the hours was unknown in Europe till the end of the 12th century; and hence the custom of employing men to proclaim the hours during night. Galileo was the first who conceived an idea that a pendulum might be used for measuring time; and Huygens was the first who put the idea in execution, by making a pendulum clock. Hooke, in the year 1660, invented a spiral spring for a watch, though a watch was far from being a new invention. Paper was made no earlier than the 14th century; and the invention of printing was a century later. Silk manufactures were long established in Greece before silk-worms were introduced there. The manufacturers were provided with raw silk from Persia; but that commerce being frequently interrupted by war, two monks, in the reign of Justinian, brought eggs of the silk-worm from Hindostan, and taught their countrymen the method of managing them. The art of reading made a very slow progress: to encourage that art in England, the capital punishment for murder was remitted if the criminal could but read, which in law language is termed *benefit of clergy*. One would imagine that the arts must have made a very rapid progress when so greatly favoured: but there is a signal proof of the contrary; for so small an edition of the Bible as 600 copies, translated into English in the reign of Henry VIII., was not wholly sold off in three years.

The discoveries of the Portuguese on the west coast of Africa is a remarkable instance of the slow progress of arts. In the beginning of the 15th century they were totally ignorant of that coast beyond Cape Non, 28 degrees north latitude. In 1410 the celebrated Prince Henry of Portugal fitted out a fleet for discoveries, which proceeded along the coast to Cape Bajadore, in 28 degrees,

but had not courage to double it. In 1418 Tristan Vaz discovered the island Porto Santo; and the year after the island Madeira was discovered. In 1439 a Portuguese captain doubled Cape Bajadore; and the next year the Portuguese reached Cape Blanco, lat. 20 degrees. In 1446 Nuna Tristan doubled Cape de Verde, lat. 14. 40. In 1448 Don Gonzallo Vallo took possession of the Azores. In 1449 the islands of Cape de Verde were discovered for Don Henry. In 1471 Pedro d'Escovar discovered the island St Thomas and Prince's Island. In 1484 Diego Cam discovered the kingdom of Congo. In 1486 Bartholomew Diaz, employed by John II. of Portugal, doubled the Cape of Good Hope, which he called *Cabo Tormentoso*, from the tempestuous weather he found in the passage.

The progress of art seldom fails to be rapid when a people happen to be roused out of a torpid state by some fortunate change of circumstances. Prosperity, contrasted with former abasement, gives to the mind a spring, which is vigorously exerted in every new pursuit. The Athenians made but a mean figure under the tyranny of Pisistratus, but upon regaining freedom and independence they were converted into heroes. Miletus, a Greek city of Ionia, being destroyed by the king of Persia, and the inhabitants made slaves, the Athenians, deeply affected with the misery of their brethren, boldly attacked the king in his own dominions, and burnt the city of Sardis. In less than ten years after, they gained a signal victory at Marathon; and, under Themistocles, made head against that prodigious army with which Xerxes threatened utter ruin to Greece. Such prosperity produced its usual effects: arts flourished with arms, and Athens became the chief theatre for sciences, as well as for fine arts. The reign of Augustus Cæsar, which put an end to the rancour of civil war, and restored peace to Rome, with the comforts of society, proved an auspicious era for literature, and produced a cloud of Latin historians, poets, and philosophers, to whom the moderns are indebted for their taste and talents. One who makes a figure rouses emulation in all: one catches fire from another, and the national spirit is everywhere triumphant; classical works are composed, and useful discoveries made in every art and science. With regard to Rome, it is true that the Roman government under Augustus was in effect despotic; but despotism in that single instance made no obstruction to literature, it having been the policy of that reign to hide power as much as possible. A similar revolution happened in Tuscany about three centuries ago. That country having been divided into a number of small republics, the people, excited by mutual hatred between small nations in close neighbourhood, became ferocious and bloody, flaming with revenge for the slightest offence. These republics being united under the great duke of Tuscany, enjoyed the sweets of peace in a mild government. That comfortable revolution, which made the deeper impression by a retrospect of recent calamities, roused the national spirit, and produced ardent application to arts and literature. The restoration of the royal family in England, which put an end to a cruel and envenomed civil war, promoted improvements of every kind; arts and industry made a rapid progress among the people, though left to themselves by a weak and fluctuating administration. Had the nation, upon that favourable turn of fortune, been blessed with a succession of able and virtuous princes, to what a height might not arts and sciences have been carried!

Another cause of activity and animation is the being engaged in some important action of doubtful issue,—a struggle for liberty, the resisting a potent invader, or the like. Greece, divided into small states frequently at war with each other, advanced literature and the fine arts to

Useful
Arts.

unrivalled perfection. The Corsicans, while engaged in a perilous war for defence of their liberties, exerted a vigorous national spirit; they founded a university for arts and sciences, a public library, and a public bank. After a long stupor during the dark ages of Christianity, arts and literature revived among the turbulent states of Italy. The Royal Society in London, and the Academy of Sciences in Paris, were both of them instituted after civil wars that had animated the people and roused their activity.

In a country thinly peopled, where even necessary arts want hands, it is common to see one person exercising more arts than one. In every populous country, even simple arts are split into parts, and each part has an artist appropriated to it. In the large towns of ancient Egypt a physician was confined to a single disease. In mechanic arts that method is excellent. As a hand confined to a single operation becomes both expert and expeditious, a mechanic art is perfected by having its different operations distributed among the greatest number of hands: many hands are employed in making a watch, and a still greater number in manufacturing a web of woollen cloth. Various arts or operations carried on by the same man invigorate his mind, because they exercise different faculties; and as he cannot be equally expert in every art or operation, he is frequently reduced to supply want of skill by thought and invention. Constant application, on the contrary, to a single operation, confines the mind to a single object, and excludes all thought and invention. In such a train of life the operator becomes dull and stupid, like a beast of burden. The difference is visible in the manners of the people. In a country where, from want of hands, several occupations must be carried on by the same person, the people are knowing and conversable: in a populous country, where manufactures flourish, they are ignorant and unsociable. The same effect is equally visible in countries where an art or manufacture is confined to a certain class of men. It is visible in Hindostan, where the people are divided into castes, which never mix even by marriage, and where every man follows his father's trade. The Dutch lint-boors are a similar instance: the same family carries on the trade from generation to generation, and are accordingly ignorant and brutish even beyond other Dutch peasants.

Useful arts pave the way to fine arts. Men upon whom the former had bestowed every convenience, turned their thoughts to the latter. Beauty was studied in objects of sight; and men of taste attached themselves to the fine arts, which multiplied their enjoyments and improved their benevolence. Sculpture and painting made an early figure in Greece, which afforded plenty of beautiful originals to be copied in these imitative arts. Statuary, a more simple imitation than painting, was sooner brought to perfection. The statue of Jupiter by Phidias, and of Juno by Polycletus, though the admiration of all the world, were executed long before the art of light and shade was known. Apollodorus, and Zeuxis his disciple, who flourished in the 95th olympiad, were the first who figured in that art. Another cause concurred to advance statuary before painting in Greece, viz. a great demand for statues of their gods. Architecture, as a fine art, made a slower progress. Proportions, upon which its elegance chiefly depends, cannot be accurately ascertained, but by an infinity of trials in great buildings. A model cannot be relied on; for a large and a small building, even of the same form, require different proportions.

FINE ARTS.

The term Fine Arts may be viewed as embracing all those arts in which the powers of imitation or invention

are exerted, chiefly with a view to the production of pleasure by the immediate impression which they make on the mind. But the phrase has of late, we think, been restricted to a narrower and more technical signification; namely, to painting, sculpture, engraving, and architecture, which appeal to the eye as the medium of pleasure; and, by way of eminence, to the two first of these arts. In the following observations we shall adopt this limited sense of the term; and shall endeavour to develop the principles upon which the great masters have proceeded, and also to inquire, in a more particular manner, into the state and probable advancement of these arts in this country.

The great works of art at present extant, and which may be regarded as models of perfection in their several kinds, are the Greek statues—the pictures of the celebrated Italian masters—those of the Dutch and Flemish schools—to which we may add the comic productions of our own countryman Hogarth. These all stand unrivalled in the history of art; and they owe their pre-eminence and perfection to one and the same principle,—*the immediate imitation of nature*. This principle predominated equally in the classical forms of the antique and in the grotesque figures of Hogarth: the perfection of art in each arose from the truth and identity of the imitation with the reality; the difference was in the subjects—there was none in the mode of imitation. Yet the advocates for the *ideal system of art* would persuade their disciples, that the difference between Hogarth and the antique does not consist in the different forms of nature which they imitated, but in this, that the one is like and the other unlike nature. This is an error the most detrimental perhaps of all others, both to the theory and practice of art. As, however, the prejudice is very strong and general, and supported by the highest authority, it will be necessary to go somewhat elaborately into the question in order to produce an impression on the other side.

What has given rise to the common notion of the *ideal*, as something quite distinct from *actual* nature, is probably the perfection of the Greek statues. Not seeing among ourselves any thing to correspond in beauty and grandeur, either with the features or form of the limbs in these exquisite remains of antiquity, it was an obvious, but a superficial conclusion, that they must have been created from the idea existing in the artist's mind, and could not have been copied from any thing existing in nature. The contrary, however, is the fact. The general form, both of the face and figure, which we observe in the old statues, is not an ideal abstraction, is not a fanciful invention of the sculptor, but is as completely local and national (though it happens to be more beautiful) as the figures on a Chinese screen, or a copperplate engraving of a negro chieftain in a book of travels. It will not be denied that there is a difference of physiognomy as well as of complexion in different races of men. The Greek form appears to have been naturally beautiful, and they had, besides, every advantage of climate, of dress, of exercise, and modes of life to improve it. The artist had also every facility afforded him in the study and knowledge of the human form; and their religious and public institutions gave him every encouragement in the prosecution of this art. All these causes contributed to the perfection of these noble productions; but we should be inclined principally to attribute the superior symmetry of form common to the Greek statues, in the first place, to the superior symmetry of the models in nature; and in the second, to the more constant opportunities for studying them. If we allow, also, for the superior genius of the people, we shall not be wrong; but this superiority consisted in their peculiar susceptibility to the impres-

Fine Arts. sions of what is beautiful and grand in nature. It may be thought an objection to what has just been said, that the antique figures of animals, &c., are as fine, and proceed on the same principles, as their statues of gods or men. But all that follows from this seems to be, that their art had been perfected in the study of the human form, the test and proof of power and skill; and was then transferred easily to the general imitation of all other objects, according to their true characters, proportions, and appearances. As a confirmation of these remarks, the antique portraits of individuals were often superior even to the personifications of their gods. We think that no unprejudiced spectator of real taste can hesitate for a moment in preferring the head of the Antinous, for example, to that of the Apollo. And in general it may be laid down as a rule, that the most perfect of the antiques are the most simple,—those which affect the least action, or violence of passion,—which repose the most on natural beauty of form, and a certain expression of sweetness and dignity, that is, which remain most nearly in that state in which they could be copied from nature without straining the limbs or features of the individual, or racking the invention of the artist. This tendency of Greek art to repose has indeed been reproached with insipidity by those who had not a true feeling of beauty and sentiment. We, however, prefer these models of habitual grace or internal grandeur to the violent distortions of suffering in the Laocoon, or even to the supercilious air of the Apollo. The Niobe, more than any other antique head, combines truth and beauty with deep passion. But here the passion is fixed, intense, habitual;—it is not a sudden or violent gesticulation, but a settled mould of features; the grief it expresses is such as might almost turn the human countenance itself into marble!

In general, then, we would be understood to maintain, that the beauty and grandeur so much admired in the Greek statues were not a voluntary fiction of the brain of the artist, but existed substantially in the forms from which they were copied, and by which the artist was surrounded. A striking authority in support of these observations, which has in some measure been lately discovered, is to be found in the *Elgin marbles*, taken from the Acropolis at Athens, and supposed to be the works of the celebrated Phidias. The process of fastidious refinement and indefinite abstraction is certainly not visible there. The figures have all the ease, the simplicity, and variety, of individual nature. Even the details of the subordinate parts, the loose hanging folds in the skin, the veins under the belly or on the sides of the horses, more or less swelled as the animal is more or less in action, are given with scrupulous exactness. This is true nature and true art. In a word, these invaluable remains of antiquity are precisely like casts taken from life. The *ideal* is not the preference of that which exists only in the mind to that which exists in nature; but the preference of that which is fine in nature to that which is less so. There is nothing fine in art but what is taken almost immediately, and, as it were, in the mass, from what is finer in nature. Where there have been the finest models in nature, there have been the finest works of art.

As the Greek statues were copied from Greek forms, so Raphael's expressions were taken from Italian faces; and we have heard it remarked, that the women in the streets at Rome seem to have walked out of his pictures in the Vatican.

Sir Joshua Reynolds constantly refers to Raphael as the highest example in modern times (at least with one exception) of the grand or ideal style; and yet he makes the essence of that style to consist in the embodying of an abstract or general idea, formed in the mind of the artist

by rejecting the peculiarities of individuals, and retaining only what is common to the species. Nothing can be more inconsistent than the style of Raphael with this definition. In his Cartoons, and in his groupes in the Vatican, there is hardly a face or figure which is any thing more than fine individual nature finely disposed and copied. The late Mr Barry, who could not be suspected of prejudice on this side of the question, speaks thus of them: "In Raphael's pictures (at the Vatican) of the *Dispute of the Sacrament*, and the *School of Athens*, one sees all the heads to be entirely copied from particular characters in nature, nearly proper for the persons and situations which he adapts them to; and he seems to me only to add and take away what may answer his purpose in little parts, features, &c.; conceiving, while he had the head before him, ideal characters and expressions, which he adapts these features and peculiarities of face to. This attention to the particulars which distinguish all the different faces, persons, and characters, the one from the other, gives his pictures quite the verity and unaffected dignity of nature, which stamp the distinguishing differences betwixt one man's face and body and another's."

If any thing is wanting to the conclusiveness of this testimony, it is only to look at the pictures themselves; particularly the *Miracle of the Conversion*, and the *Assembly of Saints*, which are little else than a collection of divine portraits, in natural and expressive attitudes, full of the loftiest thought and feeling, and as varied as they are fine. It is this reliance on the power of nature which has produced those masterpieces by the prince of painters, in which expression is all in all;—where one spirit—that of truth—pervades every part, brings down heaven to earth, mingles cardinals and popes with angels and apostles,—and yet blends and harmonizes the whole by the true touches and intense feeling of what is beautiful and grand in nature. It is no wonder that Sir Joshua, when he first saw Raphael's pictures in the Vatican, was at a loss to discover any great excellence in them, if he was looking out for his theory of the *ideal*,—of neutral character and middle forms.

There is more an appearance of abstract grandeur of form in Michael Angelo. He has followed up, has enforced, and expanded, as it were, a preconceived idea, till he sometimes seems to tread on the verge of caricature. His forms, however, are not *middle*, but *extreme* forms, massy, gigantic, supernatural. They convey the idea of the greatest size and strength in the figure, and in all the parts of the figure. Every muscle is swollen and turgid. This tendency to exaggeration would have been avoided if Michael Angelo had recurred more constantly to nature, and had proceeded less on a scientific knowledge of the structure of the human body; for science gives only the positive form of the different parts, which the imagination may afterwards magnify as it pleases; but it is nature alone which combines them with perfect truth and delicacy, in all the varieties of motion and expression. It is fortunate that we can refer, in illustration of our doctrine, to the admirable fragment of the Theseus at Lord Elgin's, which shows the possibility of uniting the grand and natural style in the highest degree. The form of the limbs, as affected by pressure or action, and the general sway of the body, are preserved with the most consummate mastery. We should prefer this statue as a model for forming the style of the student to the Apollo, which strikes us as having something of a theatrical appearance; or to the Hercules, in which there is an ostentatious and over-laboured display of anatomy. This last figure is so overloaded with sinews, that it has been suggested as a doubt, whether, if life could be put into it, it would be able to move. Grandeur of conception, truth of nature, and pu-

Fine Arts. rity of taste, seem to have been at their height when the masterpieces which adorned the Temple of Minerva at Athens, of which we have only these imperfect fragments, were produced. Compared with these, the later Greek statues display a more elaborate workmanship, more of the artifices of style. The several parts are more uniformly balanced, made more to tally like modern periods; each muscle is more equally brought out, and more highly finished as a part, but not with the same subordination of each part to the whole. If some of these wonderful productions have a fault, it is the want of that entire and naked simplicity which pervades the whole of the *Elgin marbles*.

Work of the Grecian and Italian artists. Having spoken here of the Greek statues, and of the works of Raphael and Michael Angelo, as far as relates to the imitation of nature, we shall attempt to point out, to the best of our ability, and as concisely as possible, what we conceive to be their general and characteristic excellences. The ancients excelled in beauty of form; Michael Angelo in grandeur of conception; Raphael in expression. In Raphael's faces, particularly his women, the expression is very superior to the form; in the ancient statues the form is the principal thing. The interest which the latter excite is in a manner external; it depends on a certain grace and lightness of appearance, joined with exquisite symmetry and refined susceptibility to voluptuous emotions; but there is in general a want of pathos. In their looks we do not read the workings of the heart; by their beauty they seem raised above the sufferings of humanity; by their beauty they are deified. The pathos which they exhibit is rather that of present and physical distress, than of deep internal sentiment. What has been remarked of Leonardo da Vinci, is also true of Raphael, that there is an angelic sweetness and tenderness in his faces, in which human frailty and passion are purified by the sanctity of religion. The ancient statues are finer objects for the eye to contemplate; they represent a more perfect race of physical beings, but we have little sympathy with them. In Raphael, all our natural sensibilities are heightened and refined by the sentiments of faith and hope, pointing mysteriously to the interests of another world. The same intensity of passion appears also to distinguish Raphael from Michael Angelo. Michael Angelo's forms are grander, but they are not so informed with expression. Raphael's, however ordinary in themselves, are full of expression, "even to overflowing;" every nerve and muscle is impregnated with feeling,—bursting with meaning. In Michael Angelo, on the contrary, the powers of body and mind appear superior to any events that can happen to them; the capacity of thought and feeling is never full, never strained or tasked to the extremity of what it will bear. All is in a lofty repose and solitary grandeur, which no human interest can shake or disturb. It has been said that Michael Angelo painted *man*, and Raphael *men*; that the one was an epic, the other a dramatic painter. But the distinction we have stated is, perhaps, truer and more intelligible, viz. that the one gave greater dignity of form, and the other greater force and refinement of expression. Michael Angelo, in fact, borrowed his style from sculpture. He represented, in general, only single figures (with subordinate accompaniments), and had not to express the conflicting actions and passions of a multitude of persons. It is therefore a mere truism to say that his compositions are not dramatic. He is much more picturesque than Raphael. The whole figure of his *Jeremiah* droops and hangs down like a majestic tree surcharged with showers. His drawing of the human form has the characteristic freedom and boldness of Titian's landscapes.

After Michael Angelo and Raphael, there is no doubt

that Leonardo da Vinci and Correggio are the two painters, in modern times, who have carried historical expression to the highest ideal perfection; and yet it is equally certain that their heads are carefully copied from faces and expressions in nature. Leonardo excelled principally in his women and children. We find, in his female heads, a peculiar charm of expression; a character of natural sweetness and tender playfulness, mixed up with the pride of conscious intellect and the graceful reserve of personal dignity. He blends purity with voluptuousness; and the expression of his women is equally characteristic of "the mistress or the saint." His pictures are worked up to the height of the idea he had conceived, with an elaborate felicity; but this idea was evidently first suggested, and afterwards religiously compared with nature. This was his excellence. His fault is, that his style of execution is too mathematical; that is, his pencil does not follow the graceful variety of the details of objects, but substitutes certain refined gradations, both of form and colour, producing equal changes in equal distances, with a mechanical uniformity. Leonardo was a man of profound learning as well as genius, and perhaps transferred too much of the formality of science to his favourite art.

The masterpieces of Correggio have the same identity with nature, the same stamp of truth. He has indeed given to his pictures the utmost softness and refinement of outline and expression; but this idea, at which he constantly aimed, is filled up with all the details and varieties which such heads would have in nature. So far from any thing like a naked abstract idea, or middle form, the *individuality* of his faces has something peculiar in it, even approaching the grotesque. He has endeavoured to impress habitually on the countenance those undulating outlines which rapture or tenderness leave there, and has chosen for this purpose those forms and proportions which most obviously assisted his design.

As to the colouring of Correggio, it is nature itself. Not only is the general tone perfectly true, but every speck and particle is varied in colour, in relief, in texture, with a care, a felicity, and an effect, which is almost magical. His light and shade are equally admirable. No one else, perhaps, ever gave the same harmony and roundness to his compositions. So true are his shadows,—equally free from coldness, opacity, or false glare;—so clear, so broken, so airy, and yet so deep, that if you hold your hand so as to cast a shadow on any part of the flesh which is in the light, this part, so shaded, will present exactly the same appearance which the painter has given to the shadowed part of the picture. Correggio, indeed, possessed a greater variety of excellences in the different departments of his art than any other painter; and yet it is remarkable, that the impression which his pictures leave upon the mind of the common spectator is monotonous and comparatively feeble. His style is in some degree mannered and confined. For instance, he is without the force, passion, and grandeur of Raphael, who, however, possessed his softness of expression, but of expression only; and in colour, in light and shade, and other qualities, was quite inferior to Correggio. We may, perhaps, solve this apparent contradiction by saying, that he applied the power of his mind to a greater variety of objects than others; but that this power was still of the same character; consisting in a certain exquisite sense of the harmonious, the soft and graceful in form, colour, and sentiment, but with a deficiency of strength, and a tendency to effeminacy in all these.

After the names of Raphael and Correggio, we shall mention that of Guido, whose female faces are exceedingly beautiful and ideal, but altogether commonplace and vapid compared with those of Raphael or Correggio; and

Fine Arts. they are so for no other reason but that the general idea they convey is not enriched and strengthened by an intense contemplation of nature. For the same reason, we can conceive nothing more unlike the antique than the figures of Nicholas Poussin, except as to the preservation of the costume; and it is perhaps chiefly owing to the habit of studying his art at second-hand, or by means of scientific rules, that the great merits of that able painter, whose understanding and genius are unquestionable, are confined to his choice of subjects for his pictures, and his manner of telling the story. His landscapes, which he probably took from nature, are superior as paintings to his historical pieces. The faces of Poussin want natural expression, as his figures want grace; but the back-grounds of his historical compositions can scarcely be surpassed. In his *Plague of Athens*, the very buildings seem stiff with horror. His giants, seated on the top of their fabled mountains, and playing on their Pan pipes, are as familiar and natural as if they were the ordinary inhabitants of the scene. The finest of his landscapes is his picture of the *Deluge*. The sun is just seen, wan and drooping in his course. The sky is bowed down with a weight of waters, and heaven and earth seem mingling together.

Titian is at the head of the Venetian school. He is the first of all colourists. In delicacy and purity Correggio is equal to him, but his colouring has not the same warmth and gusto in it. Titian's flesh-colour partakes of the glowing nature of the climate, and of the luxuriousness of the manners of his country. He represents objects not through a merely lucid medium, but as if tinged with a golden light. Yet it is wonderful in how low a tone of local colouring his pictures are painted,—how rigidly his means are husbanded. His most gorgeous effects are produced, not less by keeping down than by heightening his colours; the fineness of his gradations adds to their variety and force; and, with him, truth is the same thing as splendour. Every thing is done by the severity of his eye, by the patience of his touch. He is enabled to keep pace with nature by never hurrying on before her; and as he forms the broadest masses out of innumerable varying parts and minute strokes of the pencil, so he unites and harmonizes the strongest contrasts by the most imperceptible transitions. Every distinction is relieved and broken by some other intermediate distinction, like half-notes in music; and yet all this accumulation of endless variety is so managed as only to produce the majestic simplicity of nature, so that to a common eye there is nothing extraordinary in his pictures, any more than in nature itself. It is, we believe, owing to what has been here stated, that Titian is, of all painters, at once the easiest and the most difficult to copy. He is the most difficult to copy perfectly, for the artifice of his colouring and execution is hid in its apparent simplicity; and yet the knowledge of nature, and the arrangement of the forms and masses in his pictures, are so masterly, that any copy made from them, even the rudest outline or sketch, can hardly fail to have a look of high art. Because he was the greatest colourist in the world, this, which was his most prominent, has, for shortness, been considered as his only excellence; and he has been said to have been ignorant of drawing. What he was, generally speaking, deficient in, was invention or composition, though even this appears to have been more from habit than want of power; but his drawing of actual forms, where they were not to be put into momentary action, or adapted to a particular expression, was as fine as possible. His drawing of the forms of inanimate objects is unrivalled. His trees have a marked character and physiognomy of their own, and exhibit an appearance of strength or flexibility, solidity or lightness, as if they were endued with conscious

power and purposes. Character was another excellence which Titian possessed in the highest degree. It is scarcely speaking too highly of his portraits to say, that they have as much expression, that is, convey as fine an idea of intellect and feeling, as the historical heads of Raphael. The chief difference appears to be, that the expression in Raphael is more imaginary and contemplative, and in Titian more personal and constitutional. The heads of the one seem thinking more of some event or subject, those of the other to be thinking more of themselves. In the portraits of Titian, as might be expected, the Italian character always predominates; there is a look of piercing sagacity, of commanding intellect, of acute sensibility, which it would be in vain to seek for in any other portraits. The daring spirit and irritable passions of the age and country are distinctly stamped upon their countenances, and can be as little mistaken as the costume which they wear. The portraits of Raphael, though full of profound thought and feeling, have more of common humanity about them. Titian's portraits are the most historical that ever were painted; and they are so for this reason, that they have most consistency of form and expression. His portraits of Hippolyto de Medici, and of a young Neapolitan nobleman, lately in the gallery of the Louvre, are a striking contrast in this respect. All the lines of the face in the one, the eye-brows, the nose, the corners of the mouth, the contour of the face, present the same sharp angles, the same acute, edgy, contracted, violent expression. The other portrait has the finest expansion of feature and outline, and conveys the most exquisite idea possible of mild, thoughtful sentiment. The consistency of the expression constitutes as great a charm in Titian's portraits as the harmony of the colouring. The similarity sometimes objected to his heads is partly national, and partly arises from the class of persons whom he painted. He painted only Italians; and in his time it rarely happened that any but persons of the highest rank, senators or cardinals, sat for their pictures. The similarity of costume of the dress, the beard, &c. also adds to the similarity of their appearance. It adds at the same time to their picturesque effect; and the alteration in this respect is one circumstance among others that has been injurious, not to say fatal, to modern art. This observation is not confined to portrait; for the hired dresses with which our historical painters clothe their figures sit no more easily on the imagination of the artist, than they do gracefully on the lay-figures over which they are thrown.

Giorgioni, Paul Veronese, Tintoret, and the Bassans, are the remaining great names of the Venetian school. The excellence of all of them consisted in their bold, masterly, and striking imitation of nature. Their want of *ideal form* and elevated character is, indeed, a constant subject of reproach against them. Giorgioni takes the first place among them; for he was in some measure the master of Titian, whereas the others were only his disciples. The Carraccis, Domenichino, and the rest of the Bolognese school, formed themselves on a principle of combining the excellences of the Roman and Venetian painters, in which they for a while succeeded to a considerable degree; but they degenerated and dwindled away into absolute insignificance, in proportion as they departed from nature, or the great masters who had copied her, to mould their works on academic rules, and the phantoms of abstract perfection.

Rubens is the prince of the Flemish painters. Of all Flemish the great painters, he is perhaps the most artificial,—the and Du one who painted most from his own imagination,—and, painters what was almost the inevitable consequence, the most of a mannerist. He had neither the Greek forms to study

from, nor the Roman expression, nor the high character, picturesque costume, and sun-burnt hues which the Venetian painters had immediately before them. He took, however, what circumstances presented to him,—a fresher and more blooming tone of complexion, arising from moister air and a colder climate. To this he added the congenial splendour of reflected lights and shadows cast from rich drapery; and he made what amends he could for the want of expression, by the richness of his compositions, and the fantastic variety of his allegorical groups. Both his colouring and his drawing were, however, ideal exaggerations. But both had particular qualities of the highest value. He has given to his flesh greater transparency and freshness than any other painter; and this excellence he had from nature. One of the finest instances will be found in his *Peasant Family going to Market*, in which the figures have all the bloom of health upon their countenances; and the very air of the surrounding landscape strikes sharp and wholesome on the sense. Rubens had another excellence; he has given all that relates to the expression of motion in his allegorical figures, in his children, his animals, even in his trees, to a degree which no one else has equalled, or indeed approached. His drawing is often deficient in proportion, in knowledge, and in elegance, but it is always picturesque. The drawing of N. Poussin, on the contrary, which has been much cried up, is merely learned and anatomical: he has a knowledge of the structure and measurements of the human body, but very little feeling of the grand, or beautiful, or striking in form. All Rubens' forms have ease, freedom, and excessive elasticity. In the grotesque style of history,—as in the groups of satyrs, nymphs, bacchantes, and animals, where striking contrasts of form are combined with every kind of rapid and irregular movement,—he has not a rival. Witness his Silenus at Blenheim, where the lines seem drunk and staggering; and his procession of Cupids riding on animals at Whitehall, with that adventurous leader of the infantine crew, who, with a spear, is urging a lion, on which he is mounted, over the edge of the world; for beyond we only see a precipice of clouds and sky. Rubens' power of expressing motion perhaps arose from the facility of his pencil, and his habitually trusting a good deal to memory and imagination in his compositions; for this quality can be given in no other way. His portraits are the least valuable productions of his pencil. His landscapes are often delightful, and appear like the work of fairy hands.

It remains to speak of Vandyke and Rembrandt, the one the disciple of Rubens, the other the entire founder of his own school. It is not possible for two painters to be more opposite. The characteristic merits of the former are very happily summed up in a single line of a poetical critic, where he speaks of

The soft precision of the clear Vandyke.

The general object of this analysis of the works of the great masters has been to show that their pre-eminence has constantly depended, not on the creation of a fantastic, abstract excellence, existing nowhere but in their own minds, but in their selecting and embodying some one view of nature, which came immediately under their habitual observation, and which their particular genius led them to study and imitate with success. This is certainly the case with Vandyke. His portraits, mostly of English women, in the collection in the Louvre, have a cool refreshing air about them, a look of simplicity and modesty even in the very tone, which forms a fine contrast to the voluptuous glow and mellow golden lustre of Titian's Italian women. There is a quality of flesh-colour in Vandyke which is to be found in no other painter, and which

exactly conveys the idea of the soft, smooth, sliding, continuous, delicately varied surface of the skin. The objects in his pictures have the least possible difference of light and shade, and are presented to the eye without passing through any indirect medium. It is this extreme purity and silvery clearness of tone, together with the facility and precision of his particular forms, and a certain air of fashionable elegance, characteristic of the age in which he flourished, that places Vandyke in the first rank of portrait painters.

If ever there was a man of genius in the art, it was Rembrandt. He might be said to have created a medium of his own, through which he saw all objects. He was the grossest and the least vulgar, that is to say, the least common-place in his grossness, of all men. He was the most downright, the least fastidious of the imitators of nature. He took any object, he cared not what, how mean soever in form, colour, and expression; and from the light and shade which he threw upon it, it came out gorgeous from his hands. As Vandyke made use of the smallest contrasts of light and shade, and painted as if in the open air, Rembrandt used the most violent and abrupt contrasts in this respect, and painted his objects as if in a dungeon. His pictures may be said to be "bright with excessive darkness." His vision had acquired a lynx-eyed sharpness from the artificial obscurity to which he had accustomed himself. "Mystery and silence hung upon his pencil." Yet he could pass rapidly from one extreme to another, and dip his colours with equal success in the gloom of night or in the blaze of the noon-day sun. In surrounding different objects with a medium of imagination, solemn or dazzling, he was a true poet; in all the rest he was a mere painter, but a painter of no common stamp. The powers of his hand were equal to those of his eye; and indeed he could not have attempted the subjects he did, without an execution as masterly as his knowledge was profound. His colours are sometimes dropped in lumps on the canvass; at other times they are laid on as smooth as glass; and he not unfrequently painted with the handle of his brush. He had an eye for all objects as far as he had seen them. His history and landscapes are equally fine in their way. His landscapes we could look at for ever, though there is nothing in them. But "they are of the earth, earthy." It seems as if he had dug them out of nature. Every thing is so true, so real, so full of all the feelings and associations which the eye can suggest to the other senses, that we immediately take as strong an affection to them as if they were our home—the very place where we were brought up. No length of time could add to the intensity of the impression they convey. Rembrandt is the least classical and the most romantic of all painters. His *Jacob's Ladder* is more like a dream than any other picture that ever was painted. The figure of Jacob himself is thrown in one corner of the picture like a bundle of clothes, while the angels hover above the darkness in the shape of airy wings.

It would be needless to prove that the generality of the Dutch painters copied from actual objects. They have become almost a bye-word for carrying this principle into its abuse, by copying every thing they saw, and having no choice or preference of one thing to another, unless that they preferred that which was most obvious and common. We forgive them. They perhaps did better in faithfully and skilfully imitating what they had seen, than in imagining what they had not seen. Their pictures at least show that there is nothing in nature, however mean or trivial, that has not its beauty, and some interest belonging to it, if truly represented. We prefer Vangoyen's views on the borders of a canal, the yellow-

Fine Arts. tufted bank and passing sail, or Ruysdael's woods and sparkling water-falls, to the most classical or epic compositions which they could have invented out of nothing; and we think that Teniers' boors, old women, and children, are very superior to the little carved ivory Venuses in the pictures of Vanderneer; just as we think Hogarth's *Marriage à la Mode* is better than his *Sigismunda*, or, as Mr Wilkie's *Card-Players* is better than his *Alfred*. We should not assuredly prefer a *Dutch Fair* by Teniers to a *Cartoon* by Raphael; but we suspect we should prefer a *Dutch Fair* by Teniers to a *Cartoon* by the same master; or we should prefer truth and nature in the simplest dress, to affectation and inanity in the most pompous disguise. Whatever is genuine in art must proceed from the impulse of nature and individual genius.

French and Spanish painters. In the French school there are but two names of high and established reputation, N. Poussin and Claude Lorraine. Of the former we have already spoken; of the latter we shall give our opinion when we come to speak of our own Wilson. We ought not to pass over the names of Murillo and Velasquez, those admirable Spanish painters. It is difficult to characterize their peculiar excellences as distinct from those of the Italian and Dutch schools. They may be said to hold a middle rank between the painters of mind and body. They express not so much thought and sentiment, nor yet the mere exterior, as the life and spirit of the man. Murillo is probably at the head of that class of painters who have treated subjects of common life. After making the colours on the canvass feel and think, the next best thing is to make them breathe and live. But there is in Murillo's pictures of this kind a look of real life, a cordial flow of native animal spirits, which we find nowhere else. We might here refer particularly to his picture of the *Two Spanish Beggar Boys*, in the collection at Dulwich College, which cannot easily be forgotten by those who have ever seen it.

Progress of art in Britain. We come now to treat of the progress of art in Britain. We shall speak first of Hogarth, both as he is the first name in the order of time that we have to boast of, and as he is the greatest comic painter of any age or country. His pictures are not imitations of still life, or mere transcripts of incidental scenes or customs; but powerful moral satires, exposing vice and folly in their most ludicrous points of view, and, with a profound insight into the weak sides of character and manners, in all their tendencies, combinations, and contrasts. There is not a single picture of his, containing a representation of merely natural or domestic scenery. His object is not so much "to hold the mirror up to nature," as "to show vice her own feature, scorn her own image." Folly is there seen at the height—the moon is at the full—it is the very error of the time. There is a perpetual collision of eccentricities, a tilt and tournament of absurdities, pampered into all sorts of affectation, airy, extravagant, and ostentatious! Yet he is as little a caricaturist as he is a painter of still life. Criticism has not done him justice, though public opinion has. His works have received a sanction which it would be vain to dispute, in the universal delight and admiration with which they have been regarded, from their first appearance to the present moment. If the quantity of amusement, or of matter for reflection, which they have afforded, is that by which we are to judge of precedence among the intellectual benefactors of mankind, there are perhaps few persons who can put in a stronger claim to our gratitude than Hogarth. The wonderful knowledge which he possessed of human life and manners is only to be surpassed (if it can be) by the powers of invention with which he has arranged his materials, and by

the mastery of execution with which he has embodied and made tangible the very thoughts and passing movements of the mind. Some persons object to the style of Hogarth's pictures, or the class to which they belong. First, Hogarth belongs to no class, or, if he belongs to any, it is to the same class as Fielding, Smollett, Vanbrugh, and Molière. Besides, the merit of his pictures does not depend on the nature of his subjects, but on the knowledge displayed of them, on the number of ideas, on the fund of observation and amusement contained in them. Make what deductions you please for the vulgarity of the subjects—yet in the research, the profundity, the absolute truth and precision of the delineation of character,—in the invention of incident, in wit and humour, in life and motion, in everlasting variety and originality,—they never have been, and probably never will be, surpassed. They stimulate the faculties, as well as amuse them. "Other pictures we see, Hogarth's we read!"¹

There is one error which has been frequently entertained on this subject, and which we wish to correct, namely, that Hogarth's genius was confined to the imitation of the coarse humours and broad farce of the lowest life. But he excelled quite as much in exhibiting the vices, the folly, and frivolity of the fashionable manners of his time. His fine ladies do not yield the palm of ridicule to his waiting-maids, and his lords and his porters are on a very respectable footing of equality. He is quite at home, either in St Giles's or St James's. There is no want, for example, in his *Marriage à la Mode*, or his *Taste in High Life*, of affectation verging into idiocy, or of languid sensibility that might

Die of a rose in aromatic pain.

Many of Hogarth's characters would form admirable illustrations of Pope's Satires, who was contemporary with him. In short, Hogarth was a painter of real, not of low life. He was, as we have said, a satirist, and consequently his pencil did not dwell on the grand and beautiful, but it glanced with equal success at the absurdities and peculiarities of high or low life, "of the great vulgar and the small."

To this it must be added, that he was as great a master of passion as of humour. He succeeded in low tragedy as much as in low or genteel comedy, and had an absolute power in moving the affections and rending the hearts of the spectators, by depicting the effects of the most dreadful calamities of human life on common minds and common countenances. Of this the *Rake's Progress*, particularly the bedlam scene, and many others, are unanswerable proofs. Hogarth's merits as a mere artist are not confined to his prints. In general, indeed, this is the case. But when he chose to take pains, he could add the delicacies of execution and colouring in the highest degree to those of character and composition; as is evident in his series of pictures, all equally well painted, of the *Marriage à la Mode*.

We shall next speak of Wilson, whose pictures may be divided into three classes,—his Italian landscapes, or imitations of the manner of Claude,—his copies of English scenery,—and his historical compositions. The first of these are, in our opinion, by much the best; and we appeal, in support of this opinion, to the *Apollo and the Seasons*, and to the *Phaeton*. The figures are of course out of the question (these being as uncouth and slovenly as Claude's are insipid and finical); but the landscape in both pictures is delightful. In looking at them we breathe the air which the scene inspires, and feel the genius of the place present to us. In the first there is the cool

¹ See an admirable essay on the genius of Hogarth, by Charles Lamb, in a periodical work called *The Reflector*.

Fine Arts. freshness of a misty spring morning; the sky, the water, the dim horizon, all convey the same feeling. The fine grey tone and varying outline of the hills; the graceful form of the retiring lake, broken still more by the hazy shadows of the objects that repose on its bosom; the light trees that expand their branches in the air; and the dark stone figure and mouldering temple, that contrast strongly with the broad clear light of the rising day,—give a charm, a truth, a force and harmony to this composition, which produce the greater pleasure the longer it is dwelt on. The distribution of light and shade resembles the effect of light on a globe. The *Phaeton* has the dazzling fervid appearance of an autumnal evening; the golden radiance streams in solid masses from behind the flickering clouds; every object is baked in the sun;—the brown fore-ground, the thick foliage of the trees, the streams, shrunk and stealing along behind the dark high banks,—combine to produce that richness and characteristic unity of effect which is to be found only in nature, or in art derived from the study and imitation of nature. These two pictures, as they have the greatest general effect, are also more carefully finished than any other pictures we have seen of his.

In general, Wilson's views of English scenery want almost every thing that ought to recommend them. The subjects he has chosen are not well fitted for the landscape-painter, and there is nothing in the execution to redeem them. Ill-shaped mountains, or great heaps of earth,—trees that grow against them without character or elegance,—motionless waterfalls,—a want of relief, of transparency and distance, without the imposing grandeur of real magnitude (which it is scarcely within the province of art to give),—are the chief features and defects of this class of his pictures. In more confined scenes the effect must depend almost entirely on the difference in the execution and the details; for the difference of colour alone is not sufficient to give relief to objects placed at a small distance from the eye. But in Wilson there are commonly no details,—all is loose and general; and this very circumstance, which might assist him in giving the massy contrasts of light and shade, deprived his pencil of all force and precision within a limited space. In general, air is necessary to the landscape-painter; and, for this reason, the lakes of Cumberland and Westmoreland afford few subjects for landscape-painting. However stupendous the scenery of that country is, and however powerful and lasting the impression which it must always make on the imagination, yet the effect is not produced merely through the medium of the eye, but arises chiefly from collateral and associated feelings. There is the knowledge of the physical magnitude of the objects in the midst of which we are placed,—the slow, improgessive motion which we make in traversing them;—there is the abrupt precipice, the torrent's roar, the boundless expanse of the prospect from the highest mountains,—the difficulty of their ascent, their loneliness and silence;—in short, there is a constant sense and superstitious awe of the collective power of matter, of the gigantic and eternal forms of nature, on which, from the beginning of time, the hand of man has made no impression, and which, by the lofty reflections they excite in us, give a sort of intellectual sublimity even to our sense of physical weakness. But there is little in all these circumstances that can be translated into the *picturesque*, which makes its appeal immediately to the eye.

Wilson's historical landscapes, his *Niobe*, *Celadon* and *Amelia*, &c. do not, in our estimation, display either true

Fine Arts. taste or fine imagination, but are affected and violent exaggerations of clumsy common nature. They are made up mechanically of the same stock of materials,—an overhanging rock, bare shattered trees, black rolling clouds, and forked lightning. The figures in the most celebrated of these are not, like the children of Niobe, punished by the gods, but like a group of rustics crouching from a hail-storm. We agree with Sir Joshua Reynolds, that Wilson's mind was not, like N. Poussin's, sufficiently imbued with the knowledge of antiquity to transport the imagination three thousand years back, to give natural objects a sympathy with preternatural events, and to inform rocks, and trees, and mountains, with the presence of a God. To sum up his general character, we may observe, that, besides his excellence in aerial perspective, Wilson had great truth, harmony, and depth of local colouring. He had a fine feeling of the proportions and conduct of light and shade, and also an eye for graceful form, as far as regards the bold and varying outlines of indefinite objects, as may be seen in his foregrounds, &c., where the artist is not tied down to an imitation of characteristic and articulate forms. In his figures, trees, cattle, and in everything having a determinate and regular form, his pencil was not only deficient in accuracy of outline, but even in perspective and actual relief. His trees, in particular, frequently seem pasted on the canvass, like botanical specimens. In fine, we cannot subscribe to the opinion of those who assert that Wilson was superior to Claude as a man of genius; nor can we discern any other grounds for this opinion than what would lead to the general conclusion,—that the more slovenly the performance the finer the picture, and that that which is imperfect is superior to that which is perfect. It might be said, on the same principle, that the coarsest sign-painting is better than the reflection of a landscape in a mirror; and the objection that is sometimes made to the mere imitation of nature cannot be made to the landscapes of Claude, for in them the graces themselves have, with their own hands, assisted in selecting and disposing every object. Is the general effect in *his* pictures injured by the details? Is the truth inconsistent with the beauty of the imitation? Does the perpetual profusion of objects and scenery, all perfect in themselves, interfere with the simple grandeur and comprehensive magnificence of the whole? Does the precision with which a plant is marked in the fore-ground take away from the air-drawn distinctions of the blue glimmering horizon? Is there any want of that endless airy space, where the eye wanders at liberty under the open sky, explores distant objects, and returns back as from a delightful journey? There is no comparison between Claude and Wilson. Sir Joshua Reynolds used to say that there would be another Raphael before there would be another Claude. His landscapes have all that is exquisite and refined in art and nature. Every thing is moulded into grace and harmony; and, at the touch of his pencil, shepherds with their flocks, temples and groves, and winding glades and scattered hamlets, rise up in never-ending succession, under the azure sky and the resplendent sun, while

Universal Pan,
Knit with the graces, and the hours in dance,
Leads on the eternal spring.—

Michael Angelo has left, in one of his sonnets, a fine apostrophe to the earliest poet of Italy:

Fain would I, to be what our Dante was,
Forego the happiest fortunes of mankind.

What landscape-painter does not feel this of Claude.¹

¹ This painter's book of studies from nature, commonly called *Liber Veritatis*, disproves the truth of the general opinion, that his landscapes are mere artificial compositions; for the finished pictures are nearly fac-similes of the original sketches.

Fine Arts.

We have heard an anecdote connected with the reputation of Gainsborough's pictures, which rests on pretty good authority. Sir Joshua Reynolds, at one of the academy dinners, speaking of Gainsborough, said to a friend, "He is undoubtedly the best English landscape-painter." "No," said Wilson, who overheard the conversation; "he is not the best landscape painter, but he is the best portrait painter in England." They were both wrong; but the story is creditable to the versatility of Gainsborough's talents.

Those of his portraits which we have seen are not in the first rank. They are, in a good measure, imitations of Vandyke, and have more an air of gentility than of nature. His landscapes are of two classes or periods, his early and his later pictures. The former are minute imitations of nature, or of painters who imitated nature, such as Ruysdael, &c., some of which have great truth and clearness. His later pictures are flimsy caricatures of Rubens, who himself carried inattention to the details to the utmost limit that it would bear. Many of Gainsborough's later landscapes may be compared to bad water-colour drawings, washed in by mechanical movements of the hand, without any communication with the eye. The truth seems to be, that Gainsborough found there was something wanting in his *early manner*, that is, something beyond the literal imitation of the details of natural objects; and he appears to have concluded rather hastily, that the way to arrive at that *something more* was to discard truth and nature altogether. His fame rests principally, at present, on his fancy pieces, cottage children, shepherd boys, &c. These have often great truth, great sweetness, and the subjects are often chosen with great felicity. We too often find, however, even in his happiest efforts, a consciousness in the turn of the limbs, and a pensive languor in the expression, which is not taken from nature. We think the gloss of art is never so ill bestowed as on such subjects, the essence of which is simplicity. It is, perhaps, the general fault of Gainsborough, that he presents us with an ideal common life, of which we have had a surfeit in poetry and romance. His subjects are softened and sentimentalized too much; it is not simple unaffected nature that we see, but nature sitting for her picture. Our artist, we suspect, led the way to that masquerade style, which piques itself on giving the air of an Adonis to the driver of a hay cart, and models the features of a milk-maid on the principles of the antique. His *Woodman's Head* is admirable. Nor can too much praise be given to his *Shepherd Boy in a Storm*, in which the unconscious simplicity of the boy's expression, looking up with his hands folded and with timid wonder,—the noisy chattering of a magpie perched above,—and the rustling of the coming storm in the branches of the trees,—produce a most delightful and romantic impression on the mind.

Gainsborough was to be considered, perhaps, rather as a man of delicate taste, and of an elegant and feeling mind, than as a man of genius; as a lover of the art rather than an artist. He devoted himself to it, with a view to amuse and soothe his mind, with the ease of a gentleman, not with the severity of a professional student. He wished to make his pictures, like himself, amiable; but a too constant desire to please almost unavoidably leads to affectation and effeminacy. He wanted that vigour of intellect which perceives the beauty of truth; and thought that painting was to be gained, like other mistresses, by flattery and smiles. It was an error which we

are disposed to forgive in one, around whose memory, Fine Arts both as an artist and a man, many fond recollections, many vain regrets, must always linger.¹

The authority of Sir Joshua Reynolds, both from his example and instructions, has had, and still continues to have, a considerable influence on the state of art in this country. That influence has been, on the whole, unquestionably beneficial in itself, as well as highly creditable to the rare talents and elegant mind of Sir Joshua; for it has raised the art of painting from the lowest state of degradation,—of dry, meagre, lifeless inanity,—to something at least respectable, and bearing an affinity to the rough strength and bold spirit of the national character. Whether the same implicit deference to his authority, which has helped to advance the art thus far, may not, among other causes, limit and retard its future progress,—whether there are not certain original errors, both in his principles and practice, which, the farther they are proceeded in, the farther they will lead us from the truth,—whether there is not a systematic bias from the right line, by which alone we can arrive at the goal of the highest perfection,—are questions well worth considering.

We shall begin with Sir Joshua's merits as an artist. There is one error which we wish to correct at setting out, because we think it important. There is not a greater or more unaccountable mistake than the supposition that Sir Joshua Reynolds owed his success or excellence in his profession to his having been the first who introduced into this country more general principles of the art, and who raised portrait to the dignity of history, from the low drudgery of copying the peculiarities, meannesses, and details of individual nature, which was all that had been attempted by his immediate predecessors. This is so far from being true, that the very reverse is the fact. If Sir Joshua did not give these details and peculiarities so much as might be wished, those who went before him did not give them at all. Those pretended general principles of the art, which, it is said, "alone give value and dignity to it," had been pushed to their extremest absurdity before his time; and it was in getting rid of the mechanical systematic monotony and *middle forms*, by the help of which Lely, Kneller, Hudson, the French painters, and others, carried on their manufactories of history and face painting, and in returning (as far as he did return) to the truth and force of individual nature, that the secret both of his fame and fortune lay. The pedantic servile race of artists whom Reynolds superseded, had carried the abstract principle of improving on nature to such a degree of refinement, that they left it out altogether, and confounded all the varieties and irregularities of form, feature, character, expression, or attitude, in the same artificial mould of fancied grace and fashionable insipidity. The portraits of Kneller, for example, seem all to have been turned in a machine; the eye-brows are arched as if by a compass, the mouth curled, and the chin dimpled; the head turned on one side, and the hands placed in the same affected position. The portraits of this mannerist, therefore, are as like one another as the dresses which were then in fashion, and have the same "dignity and value" as the full bottomed wigs which graced their originals. The superiority of Reynolds consisted in his being varied and natural, instead of being artificial and uniform. The spirit, grace, or dignity which he added to his portraits, he borrowed from nature, and not from the ambiguous quackery of rules. His feeling of truth and nature was too strong to permit him to adopt the unmeaning style of

¹ The idea of the necessity of improving upon nature, and giving what was called a *flattering likeness*, was universal in this country fifty years ago, so that Gainsborough is not to be so much blamed for tampering with his subjects.

Fine Arts. Kneller and Hudson; but his logical acuteness was not such as to enable him to detect the verbal fallacies and speculative absurdities which he had learned from Richardson and Coppel; and, from some defects in his own practice, he was led to confound negligence with grandeur. But of this hereafter.

Sir Joshua Reynolds owed his vast superiority over his contemporaries to incessant practice and habitual attention to nature, to quick organic sensibility, to considerable power of observation, and still greater taste in perceiving and availing himself of those excellences of others which lay within his own walk of art. We can by no means look upon Sir Joshua as having a claim to the first rank of genius. He would hardly have been a great painter if other greater painters had not lived before him. He would not have given a first impulse to the art; nor did he advance any part of it beyond the point where he found it. He did not present any new view of nature, nor is he to be placed in the same class with those who did. Even in colour, his pallet was spread for him by the old masters; and his eye imbibed its full perception of depth and harmony of tone from the Dutch and Venetian schools rather than from nature. His early pictures are poor and flimsy. He indeed learned to see the finer qualities of nature through the works of art, which he, perhaps, might never have discovered in nature itself. He became rich by the accumulation of borrowed wealth, and his genius was the offspring of taste. He combined and applied the materials of others to his own purpose with admirable success; he was an industrious compiler or skilful translator, not an original inventor, in art. The art would remain, in all its essential elements, just where it is if Sir Joshua had never lived. He has supplied the industry of future plagiarists with no new materials. But it has been well observed, that the value of every work of art, as well as the genius of the artist, depends not more on the degree of excellence than on the degree of originality displayed in it. Sir Joshua, however, was perhaps the most original imitator that ever appeared in the world; and the reason of this, in a great measure, was, that he was compelled to combine what he saw in art with what he saw in nature, which was constantly before him. The portrait painter is, in this respect, much less liable than the historical painter to deviate into the extremes of manner and affectation; for he cannot discard nature altogether under the excuse that *she only puts him out*. He must meet her face to face; and if he is not incorrigible, he will see something there that cannot fail to be of service to him. Another circumstance which must have been favourable to Sir Joshua was, that though not the originator *in point of time*, he was the first Englishman who transplanted the higher excellences of his profession into his own country, and had the merit, if not of an inventor, of a reformer, of the art. His mode of painting had the graces of novelty in the age and country in which he lived; and he had, therefore, all the stimulus to exertion which arose from the enthusiastic applause of his contemporaries, and from a desire to expand and refine the taste of the public.

To an eye for colour and for effects of light and shade, Sir Joshua united a strong perception of individual character,—a lively feeling of the quaint and grotesque in expression, and great mastery of execution. He had comparatively little knowledge of drawing, either as it regarded proportion or form. The beauty of some of his female faces and figures arises almost entirely from their softness and fleshiness. His pencil wanted firmness and precision. The expression, even of his best portraits, seldom implies either lofty or impassioned intellect or delicate sensibility. He also wanted grace, if grace requires simplicity. The mere negation of stiffness and forma-

lity is not grace; for looseness and distortion are not grace. His favourite attitudes are not easy and natural, but the affectation of ease and nature. They are violent deviations from a right line. Many of the figures in his fancy pieces are placed in postures in which they could not remain for an instant without extreme difficulty and awkwardness. We might instance the *Girl drawing with a Pencil*, and some others. His portraits are his best pictures, and of these his portraits of men are the best; his pictures of children are the next in value. He had fine subjects for the former, from the masculine sense and originality of character of many of the persons whom he painted; and he had also a great advantage, as far as practice went, in painting a number of persons of every rank and description. Some of the finest and most interesting are those of Dr Johnson, Goldsmith (which is, however, too much a mere sketch), Baretta, Dr Burney, John Hunter, and the inimitable portrait of Bishop Newton. The elegant simplicity of character, expression, and drawing, preserved throughout the last picture, even to the attitude and mode of handling, discover the true genius of a painter. We also remember to have seen a print of Thomas Warton, than which nothing could be more characteristic or more natural. These were all Reynolds' intimate acquaintances, and it could not be said of them that they were men of "no mark or likelihood." Their traits had probably sunk deep into the artist's mind; he painted them as pure studies from nature, copying the real image existing before him, with all its known characteristic peculiarities; and, with as much wisdom as good-nature, sacrificing the graces on the altar of friendship. They are downright portraits and nothing more, and they are valuable in proportion. In his portraits of women, on the contrary, with very few exceptions, Sir Joshua appears to have consulted either the vanity of his employers or his own fanciful theory. They have not the look of individual nature, nor have they, to compensate the want of this, either peculiar elegance of form, refinement of expression, delicacy of complexion, or gracefulness of manner. Vandyke's attitudes have been complained of as stiff and confined. Reynolds, to avoid this defect, has fallen into the contrary extreme of negligence and contortion. His female figures which aim at gentility, are twisted into that serpentine line, the idea of which he ridiculed so much in Hogarth. Indeed Sir Joshua, in his *Discourses* (see his account of Correggio), speaks of grace as if it were nearly allied to affectation. Grace signifies that which is pleasing and natural in the posture and motions of the human form, as beauty is more properly applied to the form itself. That which is stiff, inanimate, and without motion, cannot, therefore, be graceful; but to suppose that a figure, to be graceful, need only be put into some languishing or extravagant posture, is to mistake flutter and affectation for ease and elegance.

Sir Joshua's children, as we have said above, are among his *chef d'œuvres*. The faces of children have in general that want of precision of outline, that prominence of relief and strong contrast of colour, which were peculiarly adapted to his style of painting. The arch simplicity of expression, and the grotesque character which he has given to the heads of his children, were, however, borrowed from Correggio. His *Puck* is the most masterly of all these; and the colouring, execution, and character, are alike exquisite. The single figure of the *Infant Hercules* is also admirable. Many of those to which his friends have suggested historical titles are mere common portraits or casual studies. Thus the *Infant Samuel* is an innocent little child saying its prayers at the bed's feet: it has nothing to do with the story of the Hebrew prophet. The same objection will apply to many of his fancy pieces and

Fine Arts. historical compositions. There is often no connection between the picture and the subject but the name. Even his celebrated Iphigenia, beautiful as she is, and prodigal of her charms, does not answer to the idea of the story. In drawing the naked figure, Sir Joshua's want of truth and firmness of outline became more apparent; and his mode of laying on his colours, which in the face and extremities was relieved and broken by the abrupt inequalities of surface and variety of tints in each part, produced a degree of heaviness and opacity in the larger masses of flesh-colour, which can indeed only be avoided by extreme delicacy or extreme lightness of execution.

Shall we speak the truth at once? In our opinion, Sir Joshua did not possess either that high imagination, or those strong feelings, without which no painter can become a poet in his art. His larger historical compositions have been generally allowed to be most liable to objection in a critical point of view. We shall not attempt to judge them by scientific or technical rules, but make one or two observations on the character and feeling displayed in them. The highest subject which Sir Joshua has attempted was the *Count Ugolino*, and it was, as might be expected from the circumstances, a total failure. He had, it seems, painted a study of an old beggar-man's head; and some person, who must have known as little of painting as of poetry, persuaded the unsuspecting artist that it was the exact expression of Dante's Count Ugolino, one of the most grand, terrific, and appalling characters in modern fiction. Reynolds, who knew nothing of the matter but what he was told, took his good fortune for granted, and only extended his canvass to admit the rest of the figures. The attitude and expression of Count Ugolino himself are what the artist intended them to be, till they were pampered into something else by the officious vanity of friends—those of a common mendicant at the corner of a street, waiting patiently for some charitable donation. The imagination of the painter took refuge in a parish work-house, instead of ascending the steps of the Tower of Famine. The hero of Dante is a lofty, high-minded, and unprincipled Italian nobleman, who had betrayed his country to the enemy, and who, as a punishment for his crime, is shut up with his four sons in the dungeon of the citadel, where he shortly finds the doors barred against him, and food withheld. He in vain watches with eager feverish eye the opening of the door at the accustomed hour, and his looks turn to stone; his children one by one drop down dead at his feet; he is seized with blindness, and, in the agony of his despair, he gropes on his knees after them,

..... Calling each by name
For three days after they were dead.

Even in the other world he is represented with the same fierce, dauntless, unrelenting character, "gnawing the skull of his adversary, his fell repast." The subject of the *Laocoon* is scarcely equal to that described by Dante. The horror *there* is physical and momentary; in the other, the imagination fills up the long, obscure, dreary void of despair, and joins its unutterable pangs to the loud cries of nature. What is there in the picture to convey the ghastly horrors of the scene, or the mighty energy of soul with which they are borne? His picture of *Macbeth* is full of wild and grotesque images; and the apparatus of the witches contains a very elaborate and well-arranged inventory of dreadful objects. His Cardinal Beaufort is a fine display of rich mellow colouring; and there is something gentlemanly and Shakspearian in the king and the attendant nobleman. At the same time we think the expression of the cardinal himself is too much one of physical horror, a canine gnashing of the teeth, like a man strangled. This is not the best style of history. Mrs

Siddons as the *Tragic Muse* is neither the tragic muse nor Mrs Siddons; and we have still stronger objections to *Garrick between Tragedy and Comedy*.

There is a striking similarity between Sir Joshua Reynolds' theory and his practice; and as each of these has been appealed to in support of the other, it is necessary that we should examine both. Sir Joshua's practice was generally confined to the illustration of that part of his theory which relates to the more immediate imitation of nature; and it is to what he says on this subject that we shall chiefly direct our observations at present.

He lays it down as a general and invariable rule, that "*the great style in art, and the most PERFECT IMITATION OF NATURE, consists in avoiding the details and peculiarities of particular objects.*" This sweeping principle he applies almost indiscriminately to *portrait, history, and landscape*; and he appears to have been led to the conclusion itself, from supposing the imitation of particulars to be inconsistent with general rule and effect. It appears to us that the highest perfection of the art depends, not on separating, but on uniting general truth and effect with individual distinctness and accuracy.

First, It is said that the great style in painting, as it relates to the immediate imitation of external nature, consists in avoiding the details of particular objects. It consists neither in giving nor avoiding them, but in something quite different from both. Any one may avoid the details. So far there is no difference between the *Cartoons* and a common sign painting. Greatness consists in giving the larger masses and proportions with truth;—this does not prevent giving the smaller ones too. The utmost grandeur of outline, and the broadest masses of light and shade, are perfectly compatible with the utmost minuteness and delicacy of detail, as may be seen in nature. It is not, indeed, common to see both qualities combined in the imitations of nature, any more than the combination of other excellences; nor are we here saying to which the principal attention of the artist should be directed; but we deny that, considered in themselves, the absence of the one quality is necessary or sufficient to the production of the other.

If, for example, the form of the eye-brow is correctly given, it will be perfectly indifferent to the truth or grandeur of the design, whether it consists of one broad mark, or is composed of a number of hair-lines arranged in the same order. So, if the lights and shades are disposed in fine and large masses, the *breadth* of the picture, as it is called, cannot possibly be affected by the filling up of those masses with the details, that is, with the subordinate distinctions which appear in nature. The anatomical details in Michael Angelo, the ever-varying outline of Raphael, the perfect execution of the Greek statues, do not destroy their symmetry or dignity of form; and in the finest specimens of the composition of colour we may observe the largest masses combined with the greatest variety in the parts of which those masses are composed.

The *gross* style consists in giving no details, the *finical* in giving nothing else. Nature contains both large and small parts, both masses and details; and the same may be said of the most perfect works of art. The union of both kinds of excellence, of strength with delicacy, as far as the limits of human capacity and the shortness of human life would permit, is that which has established the reputation of the most successful imitators of nature. Farther, their most finished works are their best. The predominance, indeed, of either excellence in the best masters has varied according to their opinion of the relative value of these qualities,—the labour they had the time or the patience to bestow on their works,—the skill of the artist,—or the nature and extent of his subject.

But if the rule here objected to, that the careful imitation of the parts injures the effect of the whole, be once admitted, slovenliness would become another name for genius, and the most unfinished performance be the best. That such has been the confused impression left on the mind by the perusal of Sir Joshua Reynolds' *Discourses*, is evident from the practice as well as conversation of many (even eminent) artists. The late Mr Opie proceeded entirely on this principle. He left many admirable studies of portraits, particularly in what relates to the disposition and effect of light and shade; but he never finished any of the parts, thinking them beneath the attention of a great artist. He went over the whole head the second day as he had done the first, and therefore made no progress. The picture at last, having neither the lightness of a sketch nor the accuracy of a finished work, looked coarse, laboured, and heavy. Titian is the most perfect example of high finishing. In him the details are engrafted on the most profound knowledge of effect, and attention to the character of what he represented. His pictures have the exact look of nature, the very tone and texture of flesh. The variety of his tints is blended into the greatest simplicity. There is a proper degree both of solidity and transparency. All the parts hang together; every stroke tells, and adds to the effect of the rest. Sir Joshua seems to deny that Titian finished much, and says that he produced, by two or three strokes of his pencil, effects which the most laborious copyist would in vain attempt to equal. It is true, he availed himself in some degree of what is called *execution*, to facilitate his imitation of the details and peculiarities of nature; but it was to facilitate, not to supersede it. There can be nothing more distinct than execution and daubing. Titian, however, made a very moderate, though a very admirable, use of this power; and those who copy his pictures will find that the simplicity is in the results, not in the details. To conclude our observations on this head, we will only add, that while the artist thinks there is any thing to be done, either to the whole or to the parts of his picture, which can give it still more the look of nature, if he is willing to proceed, we would not advise him to desist. This rule is the more necessary to the young student, for he will relax in his attention as he grows older. And again, with respect to the subordinate parts of a picture, there is no danger that he will bestow a disproportionate degree of labour upon them, because he will not feel the same interest in copying them, and because a much less degree of accuracy will serve every purpose of deception.

Secondly, With regard to the imitation of expression, we can hardly agree with Sir Joshua, that "the perfection of portrait painting consists in giving the general idea or character without the individual peculiarities." No doubt, if we were to choose between the general character and the peculiarities of feature, we ought to prefer the former. But they are so far from being incompatible with, that they are not without some difficulty distinguishable from, each other. There is a general look of the face, a predominant expression arising from the correspondence and connection of the different parts, which it is of the first and last importance to give, and without which no elaboration of detached parts, or marking of the peculiarities of single features, is worth any thing; but which, at the same time, is not destroyed, but assisted, by the careful finishing, and still more by giving the exact outline, of each part.

It is on this point that the modern French and English schools differ, and, in our opinion, are both wrong. The English seem generally to suppose, that if they only leave out the subordinate parts, they are sure of the general

result. The French, on the contrary, as erroneously imagine, that, by attending successively to each separate part, they must infallibly arrive at a correct whole; not considering that, besides the parts, there is their relation to each other, and the general expression stamped upon them by the character of the individual, which to be seen must be felt; for it is demonstrable, that all character and expression, to be adequately represented, must be perceived by the mind, and not by the eye only. The French painters give only lines and precise differences, the English only general masses and strong effects. Hence the two nations reproach one another with the difference of their styles of art,—the one as dry, hard, and minute,—the other as gross, gothic, and unfinished; and they will probably remain for ever satisfied with each other's defects, as they afford a very tolerable fund of consolation on either side.

Much has been said of *historical portrait*; and we have no objection to this phrase, if properly understood. The giving historical truth to a portrait means, then, the representing the individual under one consistent, probable, and striking view; or showing the different features, muscles, &c. in one action, and modified by one principle. A portrait thus painted may be said to be *historical*; that is, it carries internal evidence of truth and propriety with it; and the number of individual peculiarities, as long as they are true to nature, cannot lessen, but must add to, the strength of the general impression.

It might be shown, if there were room in this place, that Sir Joshua has constructed his theory of the *ideal* in art upon the same mistaken principle of the negation or abstraction of *particular nature*. The *ideal* is not a negative, but a positive thing. The leaving out the details or peculiarities of an individual face does not make it one jot more ideal. To paint history, is to paint nature as answering to a general, predominant, or preconceived idea in the mind, of strength, beauty, action, passion, thought, &c.: but the way to do this is not to leave out the details, but to incorporate the general idea with the details; that is, to show the same expression actuating and modifying every movement of the muscles, and the same character preserved consistently through every part of the body. Grandeur does not consist in omitting the parts, but in connecting all the parts into a whole, and in giving their combined and varied action: abstract truth or ideal perfection does not consist in rejecting the peculiarities of form, but in rejecting all those which are not consistent with the character intended to be given, and in following up the same *general idea* of softness, voluptuousness, strength, activity, or any combination of these, through every ramification of the frame. But these modifications of form or expression can only be learnt from nature, and therefore the perfection of art must always be sought in nature. The ideal properly applies as much to the *idea* of ugliness, weakness, folly, meanness, vice, as of beauty, strength, wisdom, magnanimity, or virtue. The antique heads of fauns and satyrs, of Pan or Silenus, are quite as ideal as those of the Apollo or Bacchus; and Hogarth adhered to an idea of humour in his faces, as Raphael did to an idea of sentiment. But Raphael found the character of sentiment in nature as much as Hogarth did that of humour, otherwise neither of them would have given one or the other with such perfect truth, purity, force, and keeping. Sir Joshua Reynolds' *ideal*, as consisting in a mere negation of individuality, bears just the same relation to real beauty or grandeur as caricature does to true comic character.

It is owing either to a mistaken theory of elevated art, or to the want of models in nature, that the English are

Fine Arts. hitherto without any painter of serious historical subjects, who can be placed in the first rank of genius. Many of the pictures of modern artists have shown a capacity for correct and happy delineation of actual objects and domestic incidents only inferior to the masterpieces of the Dutch School. We might here mention the names of Wilkie, Collins, Heaphy, and many others. We have portrait-painters who have attained to a very high degree of excellence in all the branches of their art. In landscape, Turner has shown a knowledge of the effects of air, and of powerful relief in objects, which was never surpassed. But in the highest walk of art—in giving the movements of the finer or loftier passions of the mind, this country has not produced a single painter who has made even a faint approach to the excellence of the great Italian painters. We have, indeed, a good number of specimens of the clay-figure, the anatomical mechanism, the regular proportions measured by a two-foot rule;—large canvasses, covered with stiff figures, arranged in deliberate order, with the characters and story correctly expressed by uplifted eyes or hands, according to old receipt-books for the passions; and with all the hardness and inflexibility of figures carved in wood, and painted over in good strong body colours, that look “as if some of nature’s journeymen had made them, and not made them well.” But we still want a Prometheus to give life to the cumbrous mass,—to throw an intellectual light over the opaque image,—to embody the inmost refinements of thought to the outward eye,—to lay bare the very soul of passion. That picture is of little comparative value which can be completely *translated* into another language,—of which the description in a common catalogue conveys all that is expressed by the picture itself; for it is the excellence of every art to give what can be given by no other in the same degree. Much less is that picture to be esteemed which only injures and defaces the idea already existing in the mind’s eye,—which does not come up to the conception which the imagination forms of the subject, and substitutes a dull reality for high sentiment; for the art is in this case an incumbrance, not an assistance, and interferes with, instead of adding to, the stock of our pleasurable sensations. But we should be at a loss to point out, we will not say any English picture, but certainly any English painter, who, in heroic and classical composition, has risen to the height of his subject, and answered the expectation of the well-informed spectator, or excited the same impression by visible means as had been excited by words or by reflection.¹ That this inferiority in English art is not owing to a deficiency of genius, imagination, or passion, is proved sufficiently by the works of our poets and dramatic writers, which, in loftiness and force, are not surpassed by those of any other nation. But whatever may be the depth of internal thought and feeling in the English character, it seems to be *more internal*; and, whether this is owing to habit or physical constitution, to have comparatively a less immediate and powerful communication with the organic expression of passion,—which exhibits the thoughts and feelings in the countenance, and furnishes matter for the historic muse of painting. The English artist is instantly sensible that the flutter, grimace, and extravagance of the French physiognomy, are incompatible with high history; and we are at no loss to explain in this way, that is, from the defect of living models, how it is that the productions of the French school are marked with all the affectation of national caricature, or sink into tame and lifeless imitations of the antique. May we not

account satisfactorily for the general defects of our own historic productions in a similar way,—from a certain inertness and constitutional phlegm, which does not habitually impress the workings of the mind in correspondent traces on the countenance, and which may also render us less sensible of these outward and visible signs of passion, even when they are so impressed there? The irregularity of proportion and want of symmetry in the structure of the national features, though it certainly enhances the difficulty of infusing natural grace and grandeur into the works of art, rather accounts for our not having been able to attain the exquisite refinements of Grecian sculpture, than for our not having rivalled the Italian painters in expression.

Mr West formed no exception to, but a confirmation of, these general observations. His pictures have all that can be required in what relates to the composition of the subject; to the regular arrangement of the groups; the anatomical proportions of the human body; and the technical knowledge of expression,—as far as expression is reducible to abstract rules, and is merely a vehicle for the telling of a story; so that anger, wonder, sorrow, pity, &c. have each their appropriate and well-known designations. These, however, are but the instrumental parts of the art, the means, not the end; but beyond these Mr West’s pictures do not go. They never “snatch a grace beyond the reach of art.” They exhibit the *mask*, not the *soul*, of expression. We doubt whether, in the entire range of Mr West’s productions, meritorious and admirable as the design and composition often are, there is to be found one truly fine head. They display a total want of gusto. In Raphael, the same divine spirit breathes through every part; it either agitates the inmost frame, or plays in gentle undulations on the trembling surface. Whether we see his figures bending with all the blandishments of maternal love, or standing in the motionless silence of thought, or hurried into the tumult of action, the whole is under the impulse of deep passion. But Mr West saw hardly any thing in the human face but bones and cartilages; or, if he availed himself of the more flexible machinery of nerves and muscles, it was only by rule and method. The effect is not that which the soul of passion impresses on the countenance, and which the soul of genius alone can seize; but such as might, in a good measure, be given to wooden puppets or pasteboard figures, pulled by wires, and taught to open the mouth, or knit the forehead, or raise the eyes in a very scientific manner. In fact, there is no want of art or learning in his pictures, but of nature and feeling.

It is not long ago since an opinion was very general, that all that was wanting to the highest splendour and perfection of the arts in this country might be supplied by academies and public institutions. There are *three* ways in which academies and public institutions may be supposed to promote the fine arts; either by furnishing the best models to the student, or by holding out immediate emolument and patronage, or by improving the public taste. We shall bestow a short consideration on the influence of each.

First, a constant reference to the best models of art necessarily tends to enervate the mind, to intercept our view of nature, and to distract the attention by a variety of unattainable excellence. An intimate acquaintance with the works of the celebrated masters may indeed add to the indolent refinements of taste, but will never produce one work of original genius, one great artist. In proof of the general truth of this observation, we might

¹ If we were to make any qualification of this censure, it would be in favour of some of Mr Northcote’s compositions from early English history.

Fine Arts. cite the history of the progress and decay of art in all countries where it has flourished. It is a little extraordinary, that if the real sources of perfection are to be sought in schools, in models, and public institutions, that wherever schools, models, and public institutions have existed, there the arts should regularly disappear,—that the effect should never follow from the cause.

The Greek statues remain to this day unrivalled,—the undisputed standard of the most perfect symmetry of form. In Italy the art of painting has had the same fate. After its long and painful struggles in the time of the earlier artists, Cimabue, Ghirlandaio, Massacio, and others, it burst out with a light almost too dazzling to behold, in the works of Titian, Michael Angelo, Raphael, and Correggio; which was reflected with diminished lustre in the productions of their immediate disciples, lingered for a while with the school of the Carraccis, and expired with Guido Reni. From that period painting sunk to so low a state in Italy as to excite only pity or contempt. There is not a single name to redeem its faded glory from utter oblivion. Yet this has not been owing to any want of Dilettanti and Della Cruscan societies,—of academies of Florence, of Bologna, of Parma, and Pisa,—of honorary members and foreign correspondents—of pupils and teachers, professors and patrons, and the whole busy tribe of critics and connoisseurs.

What is become of the successors of Rubens, Rembrandt, and Vandyke? What have the French academicians done for the arts; or what will they ever do, but add intolerable affectation and grimace to centos of heads from the antique, and caricature Greek forms by putting them into opera attitudes? Nicholas Poussin is the only example on record in favour of the contrary theory, and we have already sufficiently noticed his defects. What extraordinary advances have we made in our own country in consequence of the establishment of the royal academy? What greater names has the English school to boast than those of Hogarth, Reynolds, and Wilson, who created it?

Again, we might cite, in support of our assertion, the works of Carlo Maratti, of Raphael Mengs, or of any of the effeminate school of critics and copyists, who have attempted to blend the borrowed beauties of others in a perfect whole. What do they contain, but a negation of every excellence which they pretend to combine? The assiduous imitator, in his attempts to grasp all, loses his hold of that which was placed within his reach; and, from aspiring at universal excellence, sinks into uniform mediocrity. The student who has models of every kind of excellence constantly before him, is not only diverted from that particular walk of art in which, by patient exertion, he might have obtained ultimate success, but, from having his imagination habitually raised to an overstrained standard of refinement, by the sight of the most exquisite examples in art, he becomes impatient and dissatisfied with his own attempts, determines to reach the same perfection all at once, or throws down his pencil in despair. Thus the young enthusiast, whose genius and energy were to rival the great masters of antiquity, or create a new era in the art itself, baffled in his first sanguine expectations, reposes in indolence on what others have done,—wonders how such perfection could have been achieved,—grows familiar with the minutest peculiarities of the different schools,—flutters between the splendour of Rubens and the grace of Raphael, and ends in nothing. Such was not Correggio. He saw and felt for himself; he was of no school, but had his own world of art to create. That image of truth and beauty which existed in his mind he was forced to construct for himself, without rules or models. As it had arisen in his mind from the contemplation of nature, so he could only hope to embody it to

others by the imitation of nature. We can conceive the work growing under his hands by slow and patient touches, approaching nearer to perfection, softened into finer grace, gaining strength from delicacy, and at last reflecting the pure image of nature on the canvass. Such is always the true progress of art; such are the necessary means by which the greatest works of every kind have been produced. They have been the effect of power gathering strength from exercise, and warmth from its own impulse—stimulated to fresh efforts by conscious success, and by the surprise and strangeness of a new world of beauty opening to the delighted imagination. The triumphs of art were victories over the difficulties of art; the prodigies of genius, the result of that strength which had grappled with nature. Titian copied even a plant or a piece of common drapery from the objects themselves; and Raphael is known to have made elaborate studies of the principal heads in his pictures. All the great painters of this period were thoroughly grounded in the first principles of their art; had learned to copy a face, a hand, or an eye, and had acquired patience to finish a single figure before they undertook to paint extensive compositions. They knew that though fame is represented with her head above the clouds, her feet rest upon the earth. Genius can only have its full scope where, though much may have been done, more remains to do; where models exist chiefly to show the deficiencies of art, and where the perfect idea is left to be filled up in the painter's imagination. When once the stimulus of novelty and of original exertion is wanting, generations repose on what has been done for them by their predecessors, as individuals, after a certain period, rest satisfied with the knowledge they have already acquired.

With regard to the pecuniary advantages arising from the public patronage of the arts, the plan unfortunately defeats itself; for it multiplies its objects faster than it can satisfy their claims, and raises up a swarm of competitors for the prize of genius from the dregs of idleness and dulness. The real patron is anxious to reward merit, not to encourage gratuitous pretensions to it; to see that the man of genius *takes no detriment*, that another Wilson is not left to perish for want;—not to propagate the breed of embryo candidates for fame. Offers of public and promiscuous patronage can in general be little better than a species of intellectual seduction, administering provocatives to vanity and avarice, and leading astray the youth of the nation by fallacious hopes, which can scarcely ever be realized. At the same time, the good that might be done by private taste and benevolence is in a great measure defeated. The moment that a few individuals of discernment and liberal spirit become members of a public body, they are no longer anything more than parts of a machine, which is usually wielded at will by some officious overweening pretender; their good sense and good nature are lost in a mass of ignorance and presumption; their names only serve to reflect credit on proceedings in which they have no share, and which are determined on by a majority of persons who have no interest in the arts but what arises from the importance attached to them by regular organization, and no opinions but what are dictated to them by some self-constituted judge. As far as we have had an opportunity of observing the conduct of such bodies of men, instead of taking the lead of public opinion, of giving a firm, manly, and independent tone to that opinion, they make it their business to watch all its caprices, and follow it in every casual turning. They dare not give their sanction to sterling merit struggling with difficulties, but take advantage of its success to reflect credit on their own reputation for sagacity. Their taste is a servile dependent on their vanity, and their patronage

Fine Arts
||
Arundel.

has an air of pauperism about it. Perhaps the only public patronage which was ever really useful to the arts, or worthy of them, was that which they received first in Greece, and afterwards in Italy, from the religious institutions of the country; when the artist felt himself, as it were, a servant at the altar; when his hand gave a visible form to gods or herocs, angels or apostles; and when the enthusiasm of genius was exalted by mingling with the flame of national devotion. The artist was not here degraded by being made the dependent on the caprice of wealth or fashion, but felt at once the servant and the benefactor of the public. He had to embody, by the highest efforts of his art, subjects which were sacred to the imagination and feelings of the spectators; there was a common link, a mutual sympathy, between them in their common faith. Every other mode of patronage but that which arises either from the general institutions and manners of a people, or from the real unaffected taste of individuals, must, we conceive, be illegitimate, corrupted in its source, and either ineffectual or injurious to its professed object.

Lastly, Academies and institutions may be supposed to assist the progress of the fine arts, by promoting a wider taste for them.

In general, it must happen in the first stages of the arts, that as none but those who had a natural genius for them would attempt to practise them, so none but those who had a natural taste for them would pretend to judge of or criticise them. This must be an incalculable advantage to the man of true genius; for it is no other than the privilege of being tried by his peers. In an age when con-

noisseurship had not become a fashion,—when religion, war, and intrigue, occupied the time and thoughts of the great,—only those minds of superior refinement would be led to notice the works of art, who had a real sense of their excellence; and, in giving way to the powerful bent of his own genius, the painter was most likely to consult the taste of his judges. He had not to deal with pretenders to taste, through vanity, affectation, and idleness. He had to appeal to the higher faculties of the soul,—to that deep and innate sensibility to truth and beauty, which required only fit objects to have its enthusiasm excited,—and to that independent strength of mind, which, in the midst of ignorance and barbarism, hailed and fostered genius wherever it met with it. Titian was patronized by Charles V. Count Castiglione was the friend of Raphael. These were true patrons and true critics; and, as there were no others (for the world, in general, merely looked on and wondered), there can be little doubt that such a period of dearth of factitious patronage would be most favourable to the full development of the greatest talents, and to the attainment of the highest excellence.

By means of public institutions, the number of candidates for fame and pretenders to criticism is increased beyond all calculation, while the quantity of genius and feeling remains much the same as before; with these disadvantages, that the man of original genius is often lost among the crowd of competitors who would never have become such but from encouragement and example, and that the voice of the few whom nature intended for judges is apt to be drowned in the noisy and forward suffrages of shallow smatterers in taste. (D. D.)

ARTS, MASTER OF. See DEGREES, ACADEMICAL.

ARVALES FRATRES, in *Roman Antiquity*, a college of twelve priests, instituted by Romulus, and chosen out of the most noble families, he himself being one of that body. They assisted in the sacrifices of the ambervalia, annually offered to Ceres and Bacchus for the prosperity of the fruits of the earth, when they wore on their heads crowns made of ears of corn. The original of this institution was as follows: Acca Laurentia, Romulus's nurse, was accustomed once a year to make a solemn sacrifice for a blessing on the fields, her twelve sons always assisting her in the solemnity; but at last losing one of her sons, Romulus offered himself to supply his place, and gave this small society the name of *Arvales Fratres*. This order was in great repute at Rome: they held the dignity for life, and never lost it on account of imprisonment, banishment, or any other accident.

ARVIL SUPPER, a feast or entertainment made at funerals in the north part of England. Arvil bread is the bread delivered to the poor at funeral solemnities.

ARVIRAGUS, an ancient British king, who flourished in the time of the emperor Domitian. He gained a complete victory over Claudius; but being soon after besieged in the city of Winchester, he made a treaty with the Romans, and married the emperor's daughter Genuissa. This monarch lived to a good old age: he confirmed the ancient laws, enacted new ones, and liberally rewarded persons of merit.

ARUNDEL, a borough and market-town in the rape of the same name, in the county of Sussex, 57 miles from London. It is a well-built town, on the river Arun. Adjoining to it is the magnificent castle of the dukes of Norfolk, lately repaired and fitted up at a vast expense. The market is on a Saturday. It returns two members to Parliament, chosen by the householders, who commonly pay the compliment to the duke of Norfolk of accept-

ing one on his recommendation. The population was, in 1801, 1855; in 1811, 2178; and in 1821, 2511.

ARUNDEL, *Thomas*, archbishop of Canterbury in the reigns of Richard II., Henry IV., and Henry V., was the second son of Robert, earl of Arundel and Warren, and brother of Richard, earl of Arundel, who was beheaded. At 22 years of age, from being created archbishop of Taunton, he was raised to the bishopric of Ely, on the 6th of April 1375, in the reign of Edward III. He was a great benefactor to the church and palace of this see: among other donations, he gave a curious table of massy gold, adorned with precious stones, which had been given by the king of Spain to Prince Edward, and sold by him to Bishop Arundel. In 1386 he was appointed lord chancellor of England; two years after he was translated to the see of York; and in 1396 was advanced to the archiepiscopal see of Canterbury, when he resigned the chancellorship. This was the first instance of the translation of an archbishop of York to the see of Canterbury. Scarcely was he fixed in this see, when he had a contest with the university of Oxford about the right of visitation. The affair was referred to King Richard, who determined it in favour of the archbishop. At his visitation in London he revived an old constitution, by which the inhabitants of the respective parishes were obliged to pay to their rector one halfpenny in the pound out of the rent of their houses. In the second year of his translation, a parliament being held at London, the commons, with the king's leave, impeached the archbishop, together with his brother the earl of Arundel, and the duke of Gloucester, of high treason. The archbishop was sentenced to be banished, and within forty days to depart the kingdom on pain of death. He retired, first to France, and then to the court of Rome, where Pope Boniface IX. gave him a kind reception. He was engaged in the plot to depose Richard and place the duke of Lancaster on the throne; and re-

Arundel.

Arundel turning to England along with him, he was restored to his see on that monarch's accession. In the first year of this prince's reign Arundel summoned a synod, which sat at St Paul's. The next year the commons moved that the revenues of the church might be applied to the service of the public; but Arundel opposed the measure with such vigour that it was thrown aside. In the year 1408 Arundel began to exert himself against the Lollards or Wickliffites; and his zeal for suppressing that sect carried him to several unjustifiable severities against the heads of it, particularly against Sir John Oldcastle and Lord Cobham. He also procured a synodical constitution, which forbade the translation of the Scriptures into the vulgar tongue. This prelate died at Canterbury on the 20th February 1413, of an inflammation in his throat, with which he was seized, as is pretended, whilst he was pronouncing sentence upon Lord Cobham. He was buried in the cathedral church of Canterbury, near the west end, under a monument erected by himself in his lifetime.

ARUNDELIAN MARBLES, OXFORD MARBLES, or PARIAN CHRONICLE, are ancient stones, as has been supposed, whereon is inscribed a chronicle of the city of Athens, engraven in capital letters in the island of Paros, one of the Cyclades, 264 years before Jesus Christ. They take their first name from Thomas, earl of Arundel, who procured them out of the east, or from Henry his grandson, who presented them to the university of Oxford.

The Arundelian marbles, in their perfect state, contained a chronological detail of the principal events of Greece during a period of 1318 years, beginning with Cecrops, before Christ 1582 years, and ending with the archonship of Diognetus, before Christ 264. But the chronicle of the last 90 years is lost, so that the part now remaining ends at the archonship of Diotimus, 354 years before the birth of Christ; and in this fragment the inscription is at present so much corroded and effaced, that the sense can only be discovered by very learned and industrious antiquaries, or, more properly speaking, supplied by their conjectures.

This chronicle, and many other relics of antiquity, real or pretended, were purchased in Asia Minor, in Greece, or in the islands of the archipelago, by Mr William Petty, who, in the year 1624, was sent by Thomas, earl of Arundel, for the purpose of making such collections for him in the east. They were brought into England about the beginning of the year 1629, and placed in the gardens belonging to Arundel house in London.

Soon after their arrival they excited a general curiosity, and were viewed by many inquisitive and learned men, among others by Sir Robert Cotton, who prevailed upon Selden to employ his abilities in explaining the Greek inscriptions. Selden and two of his friends, Patrick Young, or, as he styled himself in Latin, *Patricius Junius*, and Richard James, immediately commenced their operations, by cleaning and examining the marble containing the Smyranean and Magnesian league, and afterwards proceeded to the Parian chronicle. The following year Selden published a small volume in quarto, including about 39 inscriptions copied from the marbles.

In the turbulent reign of Charles I. and the subsequent usurpation, Arundel house was often deserted by the illustrious owners; and, in their absence, some of the marbles were defaced and broken, and others either stolen or used for the ordinary purposes of architecture. The chronological marble, in particular, was unfortunately broken and defaced. The upper part, containing 31 epochs, is said to have been worked up in repairing a chimney in Arundel house.

In the year 1667 the Honourable Henry Howard, afterwards duke of Norfolk, the grandson of the first collector,

presented these supposed remains of antiquity to the university of Oxford.

Selden's work becoming very scarce, Bishop Fell engaged Mr Prideaux to publish a new edition of the inscriptions, which was printed at Oxford in 1676. In 1732 Mr Maittaire obliged the public with a more comprehensive view of the marbles than either of his predecessors. Lastly, Dr Chandler published a new and improved copy of the marbles in 1763, in which he corrected the mistakes of the former editors; and in some of the inscriptions, particularly that of the Parian chronicle, supplied the *lacunæ* by many ingenious conjectures.

The Arundelian marbles have generally been regarded as a curious monument of antiquity. They were, however, discovered in some instances to be inconsistent with the most authentic historical accounts. Sir Isaac Newton and several other modern philosophers paid little or no regard to them; and their absolute authenticity has been severely questioned in an express dissertation upon the subject by Mr Robertson, published in 1788, entitled *The Parian Chronicle*. In this dissertation much ingenuity as well as learning is displayed. His doubts, the author observes, arise from the following considerations.

I. "The characters have no certain or unequivocal marks of antiquity." The Π and Z , which frequently occur in the form supposed to be the most ancient (viz. the perpendicular line of the Π on the right hand only half as long as that on the left, and the Z in the form of a prostrate Ξ), are so well known, that any modern fabricator of a Greek inscription which he intends to impose upon the world as a relic of antiquity would most probably use them in preference to the more common and ordinary forms. But the letters in the Parian chronicle have no appearance of antiquity except this very equivocal one. They do not in the least resemble the Sigeian, the Nemean, or the Delian inscriptions, which are supposed to be of a more ancient date. They differ in many respects from the letters on the Marmor Sandvicense, which, according to the learned editor of that inscription, was engraved in the year before Christ 374. They bear no sort of resemblance to the characters on the Farnesian pillars, to those of the Alexandrian manuscript, or others of a later date. They seem, continues our author, to resemble, perhaps more than any other, the letters of the alphabet taken by Montfaucon from the Marmor Cyzicenum at Venice. They are plain and simple in their form, and such as an ordinary stone-cutter of the present age would probably make if he were employed to engrave a Greek inscription according to the alphabet now in use. The small letters intermixed among the larger have, in the opinion of our author, an air of affectation and artifice rather than genuine antiquity; and he is persuaded that the antiquity of an inscription can never be proved by the mere form of the letters, because the most ancient characters may be as easily counterfeited as those which compose our present alphabets.

That the learned reader may form a competent idea of the characters in the Parian chronicle, the author has compared them with those of other inscriptions, and given what is usually termed a *fac simile*.

In regard to several *archaisms*, as they are called in this chronicle, and which our author specifies, he contends that no conclusion can be drawn from them in favour of its antiquity. What reason could there be, he asks, for introducing these into the Parian chronicle? We do not usually find them in Greek writers of the same age, or even in those of the most early date. The reign of Ptolemy Philadelphus, with the 21st year of which the date of the chronicle coincides, was not an age of rude antiquity with respect to the Greek language, being only 130 years after

Arundel-
lian
Marbles.

the time of Xenophon and Plato, when the Greek was spoken and written in its utmost purity and elegance; and we can scarcely suppose that even a stone-cutter in that refined age would have been permitted to disgrace a superb and learned monument with such barbarisms as occur in the chronicle. The archaisms, however, he remarks, are not uniformly observed in this inscription. He adduces six instances of deviation, and adds, he is almost tempted to suspect that *ἐν Παρῷ*, *ἐν Μαραθῶνι*, and other pretended archaisms, are owing to a mere affectation of antiquity, or to a corrupted dialect and pronunciation in later ages. Those archaisms, our author acknowledges, appear on other marbles; but he thinks that for that very reason they would naturally be adopted by the fabricator of a supposititious inscription; and the authenticity of those inscriptions in which they appear must be established before they can be urged in opposition to the present argument.

II. "It is not probable that the chronicle was engraved for private use." Our author thinks it an impossible supposition that such an expensive and cumbersome work could have been executed by a private citizen, either for his own amusement or for the benefit of his fellow-citizens. In the first place, a long inscription could not be engraved in marble without such an expense as few learned Greeks were able to afford; or if its author, by an uncommon felicity, was able to erect such a literary monument, the scheme would have been useless and imprudent, as all the contents of the inscription might have been published more commodiously and effectually by the common mode of writing in use at that time.

III. "The chronicle does not appear to have been engraved by public authority."

1st, The first argument in support of this opinion is, that inscriptions of that kind usually begin with a particular form, as *Η ΒΟΥΛΗ ΚΑΙ Ο ΔΗΜΟΣ*. The senate and the people; or thus, *ΕΔΟΞΕΝ ΤΗ ΒΟΥΛΗ ΚΑΙ ΤΟΙΣ ΔΗΜΟΙΣ*. It pleased the senate and the people, &c. But the Parian chronicle begins in the manner of a private man, speaking of his own performance in the first person singular. This argument, our author remarks, cannot be much affected by observing that the beginning of the inscription is obliterated; for it is necessarily implied by the words now remaining.

2dly, The facts and dates which are mentioned in this chronicle do not appear to have been extracted from any public records, or calculated to answer the purpose of authentic documents, as many eminent princes and magistrates are passed over without notice, in several instances the transactions of whole centuries are omitted, and the facts chiefly specified are not matters of general or national importance.

3dly, The Parian inscription is such a one as we can hardly suppose the magistrates or the people of Paros would have ordered to be engraved. Stately sepulchres, pillars, triumphal arches, and the like, were erected to perpetuate the glory of eminent men. The remembrance of events in which nations were interested, the succession of princes, &c. were preserved in the same manner. Leagues, decrees, and laws, were likewise engraved on marble or brass, and fixed to a pillar, the walls of a temple, or other public buildings; because such inscriptions were designed for the inspection of the people, as they essentially concerned their conduct, their property, their liberty, or their lives. But our author asks, for whom could the chronicle of Paros be intended? It contains no encomiums on any of the patriots, the heroes, or the demigods of the country, no decrees of the magistrates, no public records, no laws of state. On the contrary, it is a work of mere speculation and learning, in which the inha-

bitants of that island, especially the common people, had not the least interest or concern.

These words at the beginning, *αρχοντος ἐν Παρῷ*, would naturally lead us to suppose that the inscription related to Paros. And if so, it would have been natural for the author to have mentioned some of the most important occurrences in the history of that island. But, says this acute and learned critic, what scheme does our chronologer pursue on this occasion? Does he record the events and revolutions of his own country? Does he mention any of the battles, sieges, and treaties of the Parians; any of their public institutions; any of their poets, patriots, or warriors? Does he mention Archilochus, who was honoured by his countrymen, and distinguished as a poet in a general assembly of the Greeks? Not a syllable on any of these subjects! On the contrary, he rambles from place to place, and records the transactions of Athens, Corinth, Macedon, Lydia, Crete, Cyprus, Sicily, Persia, and other foreign countries with which Paros had no connection.

In this view the inscription seems to have been as impertinent in the island of Paros as a marble monument would be in this country recording the antiquities of France or Spain; or one in Jamaica recording the revolutions of England. But, upon supposition that the inscription is a forgery, it is easy to account for this extraordinary circumstance. A few chronological occurrences in the ancient history of Paros would not have been so interesting to the generality of readers, or so valuable in the estimation of every lover of antiquities, or, in short, so profitable to the compiler, as a general system of Grecian chronology.

IV. "The Greek and Roman writers, for a long time after the date of this work, complain that they had no chronological account of the affairs of ancient Greece." This position is confirmed by the testimony of Julius Africanus, Justin Martyr, Plutarch, Josephus, Varro, Diodorus Siculus, and others; and the following series of interrogatories is subjoined:—"Thucydides, I know, lived 140 years before the chronicle is said to have been written; but if Thucydides, as well as other writers, complained that there was nothing but uncertainty in the earlier part of Grecian history, from whence can we suppose the author of this inscription collected such a clear, determinate, and comprehensive system of chronology? If he had any sources of information which were unknown to succeeding writers, how happens it that they should all of them overlook this most considerable, most exact, most creditable author? Why did they omit this ancient account of their early ages? Why did they not copy his most memorable epochas? Why did they not produce his authority? or, at least, why did they not mention his opinion? Surely nothing, to all appearance, could be more elaborate, more important, or of higher authority, than a chronological table which was thought worthy of being engraved on marble.

V. "The chronicle is not once mentioned by any writers of antiquity." This, indeed, appears a strong argument against its authenticity. Apollodorus, an Athenian, the disciple of Aristarchus the grammarian, and Panætius the philosopher, wrote a genealogical and historical work on the early ages of Greece; but though composed 120 years after the date of the Parian chronicle, it does not contain the smallest traces of a systematical chronology. It is remarkable, too, that the chronicle of Apollodorus is quoted by Diodorus Siculus, Strabo, Plutarch, A. Gellius, Lucian, and many other writers of antiquity; while the Parian chronicle, which comprehends a more extensive period, is entirely unnoticed. It contains, however, such wonderful discoveries in ancient history, that if it had ex-

Arundel-
lian
Marbles.

isted 264 years before the Christian era, it must have excited a general attention, and been referred to as an authority by writers of succeeding times. But we do not find, in any author of antiquity, either poet or historian, geographer or chronologer, mythologist or scholiast, the most distant allusion to the Parian chronicle; though it was such a common practice among the ancients to mention the works of their predecessors, that in many books we find references and allusions to three, four, five, six, or seven hundred different authors of every denomination.

VI. "Some of the facts mentioned in the chronicle seem to have been taken from writers of a later date." Our inquirer collates several passages in the Parian chronicle with parallel passages in Greek authors, to evince that there is, in the former, an appearance of imitation, or a stronger resemblance than such as may be supposed to arise from accident; that there are likewise some improbabilities attending the account of Deucalion, as related in the Parian chronicle; and that the names of six, and, if the *lacunæ* are properly supplied, the names of twelve cities appear to have been engraved on the marble, exactly as we find them in *Ælian's Various History*. But there is not, our author observes, any imaginable reason for this particular arrangement. It does not correspond with the time of their foundation, with their situation in Ionia, with their relative importance, or with the order in which they are placed by other eminent historians. The argument by which our author endeavours to prove that the Parian chronicle has in this instance copied *Ælian's Various History*, seems decisive of the fact. He observes that six names may be transposed 720 different ways, and that 12 names admit of 479,001,600 different transpositions. Supposing, then, that there is no particular reason for one arrangement rather than another, it will follow that the chance of two authors placing them in the same order is, in the former case, as 1 to 720; and, in the latter, as 1 to 479,001,600. It is therefore, says he, utterly improbable that these names should have been placed in this order on the marble, if the author of the inscription had not transcribed them from the historian.

It may indeed be urged, with regard to this similarity of arrangement in the Parian chronicle and *Ælian's Various History*, that the inference might be the very inverse of that which is specified by our author. But that *Ælian* should have seen the Parian chronicle without once mentioning it, or that he should have exactly copied a list of towns, arranged neither according to chronological or topographical order, is indeed a supposition equally improbable with the other.

VII. "Parachronisms appear in some of the epochas, which we can scarcely suppose a Greek chronologer in the 129th olympiad would be liable to commit." After specifying these, our inquirer asks, would a writer of reputation and learning, in one of the most polished and enlightened eras of ancient Greece, commit such mistakes, in opposition to the positive attestations of the most accurate historians, in events of public notoriety? Would a private citizen or a magistrate of Paros order a crude and inaccurate series of epochas to be engraved at a great expense, and transmitted to posterity on a marble monument? It is hardly probable.

VIII. "The history of the discovery of the Parian chronicle is obscure and unsatisfactory." Our author observes that it is attended with some suspicious circumstances, and without any of those clear and unequivocal evidences which always discriminate truth from falsehood. There are no data in the inscription by which to discover the place where the marble was erected. The place likewise where it was found is not ascertained, though the generality of writers who have had occasion to mention it

have supposed that it was found in the island of Paros. If it was erected at Smyrna, as some imagine, our author asks, for what purpose does the writer mention Astynax the archon of Paros, and not one circumstance relative to Smyrna? If, adds he, it was erected at Paros, why does he not mention more archons of that city than one? or how shall we account for his profound silence with respect to all the events and revolutions which must have happened in that island, and have been infinitely more interesting to the natives than the transactions of any foreign country?

The train of circumstances by which the Parian chronicle came into the possession of Mr Petty, whom Lord Arundel had sent into the East for the purpose of collecting antiquities, as well as the subsequent conduct of Peiresc, its former owner, affords our author a strong presumption that "the inscription was actually fabricated with the view of obtaining for it a high price, upon the pretence that it was a relic of great antiquity. It is certain that there is something mysterious in the conduct of the first ostensible proprietors. These marbles had been totally unknown or unnoticed for almost 1900 years, and at last are dug out of the ground—nobody can tell us when or where!"

IX. "The literary world has been frequently imposed upon by spurious books and inscriptions, and therefore we should be extremely cautious with regard to what we receive under the venerable name of antiquity." This proposition is illustrated by a great variety of examples, and very properly exposes the forgeries which have disgraced the republic of letters in different ages; and although one of the more recent ones cited, namely, *Ossian's Poems*, be a point very far indeed from being established, yet that deceptions of this kind have been practised is an unquestionable fact.

In endeavouring, towards the end of his Dissertation, to investigate the time of the supposed forgery, he observes that the 16th century, and the prior part of the 17th, produced a multitude of grammarians, critics, and commentators, deeply versed in Grecian literature, and amply qualified for the compilation of such a chronological system as that of the Arundelian marbles. Above all, the science of chronology was particularly studied and investigated about that time: "Nunc fervet chronologia," says Scaliger in the year 1605, "omnes hoc ferrum excaffaciunt." Cassaubon treats those persons with contempt who were unacquainted with the improvements which had been made in that department of learning after the revival of letters. Innumerable systems of chronology had been published before the year 1625, from which it was easy to extract a series of memorable events, and give the compilation a Grecian dress. "The avidity," says our author, "with which all relics of antiquity were then collected, and the high price with which they were purchased, were sufficient inducements to any one, whose avarice or whose necessity was stronger than his integrity, to engrave his labours on marble, and transmit them to Smyrna, as a commodious emporium for such rarities."

The foregoing arguments are no doubt possessed of considerable force and plausibility; but they have been ably answered, and the authenticity of the Parian chronicle vindicated, by other writers; particularly the late Professor Porson, in an examination of Mr Robertson's Dissertation, in the *Monthly Review* for January 1789. See also Hewlett's Vindication, in the *Archæologia*, vol. ix.

ARUSPICES, or HARUSPICES, in *Roman Antiquity*, an order of priests who pretended to foretell future events by inspecting the entrails of victims killed in sacrifice; they were also consulted on occasion of portents and prodigies. The aruspices were also chosen from the best families;

Arundelian
Marbles

Arx
||
As.

and as their employment was of the same nature as that of the augurs, they were as much honoured. Their college, as well as those of the other religious orders, had its particular registers and records.

ARX, in the ancient military art, a town, fort, or castle, for defence of a place. The arx in ancient Rome was a distinct edifice from the capitol, though some have confounded the two.

ARX also denotes a consecrated place on the Palatine Mount, where the augurs publicly performed their office. Some will have the arx to have been the augural temple, but Varro expressly distinguishes between the two.

ARX was particularly used for a public place in Rome, set apart for the operations of the augurs; in which sense arx amounts to the same with what is otherwise called *auguraculum* and *auguratorium*, and in the camp *augurale*. Out of this arx it was that the *feciales*, or heralds, gathered the grass used in the ceremony of making leagues and treaties.

ARZEW, a seaport in the western part of the kingdom of Algiers, containing very considerable, and sometimes beautiful, remains of antiquity. There are traces of very fine ancient cisterns, though all the water used by the inhabitants is brackish. At the distance of five miles there are very fine salt pits, which serve, however, only for the supply of the neighbouring districts. Long. 1. E. Lat. 35. 52. N.

ARZILLA, a very ancient maritime town of Africa, in the kingdom of Fez, about five leagues from Tangiers. It is built at the mouth of a river, and inhabited by Moors and Jews, who carry on no trade. It was formerly a Roman colony, under the name of Julia Traducta. It afterwards fell under the government of the Goths, and was next taken by the Mahometans. Alphonso of Portugal, surnamed the African, took it by assault in 1471, and brought away the presumptive heir of the crown. After that prince came to the throne, he besieged it in 1508, with 100,000 men; but was obliged to abandon the undertaking. However, at length the Portuguese forsook it of their own accord. It is now sunk into a very small place, not containing above 1000 inhabitants.

AS, in *Antiquity*, a particular weight, consisting of 12 ounces, being the same with *libra*, or the Roman pound. The word is derived from the Greek *ais*, which, in the Doric dialect, is used for *ais*, one, q. d. an entire thing; though others will have it named *as* quasi *æs*, because made of brass.

As was also the name of a Roman coin, which was of different weight and different matters in different ages of the commonwealth. Under Numa Pompilius, according to Eusebius, the Roman money was either of wood, leather, or shells. In the time of Tullus Hostilius it was of brass, and called *as libra*, *libella*, or *pondo*, because actually weighing a pound or 12 ounces. Four hundred and twenty years after, the first Punic war having exhausted the treasury, they reduced the *as* to two ounces. In the second Punic war, Hannibal pressing very hard upon them, they reduced the *as* to half its weight, viz. to one ounce. And lastly, by the Papirian law they took away half an ounce more, and consequently reduced the *as* to the diminutive weight of half an ounce; and it is generally thought that it continued the same during the commonwealth, and even to the reign of Vespasian. The *as*, therefore, was of four different weights in the commonwealth. Its original stamp was that of a sheep, ox, or sow; but from the time of the emperors it had on one side a Janus with two faces, and on the reverse the rostrum or prow of a ship.

As was also used to denote any integer or whole; whence the English word *ace*. Thus *as* signified the

whole inheritance; whence *hæres ex asse*, the heir to the whole estate.

ASA, king of Judah, succeeded his father Abijam. He pulled down the altars erected to idols, restored the worship of the true God, and, with the assistance of Benhadad, king of Syria, took several towns from the king of Israel. He died 917 years before the Christian era, and was succeeded by Jehoshaphat.

ASAPH, St, a small episcopal city in the county of Flint, in North Wales, at the confluence of the rivers Clwd and Elwy, said to have been founded in the year 560. The situation is fine, but the town itself has a poor appearance, the houses being small and ill built. The chief objects are the cathedral, a plain building about 170 feet in length and 90 in height; the bishop's palace, a commodious but simple dwelling; and another church, in which divine service is performed in the Welsh language. The diocese consists of parts of Flintshire, Derbyshire, Montgomeryshire, Merionethshire, and comprehends a few parishes in Shropshire. The deanery, in the gift of the bishop, is a more valuable benefice than the bishopric itself. It is 209 miles from London, and 21 from Chester. No market is held there. Population, in 1801, 1513; in 1811, 1724; in 1821, 2294.

ASAR-ADDON, or ESAR-HADDON, the son of Sennacherib, succeeded his father about 712 years before the Christian era, and united the kingdoms of Nineveh and Babylon. He rendered himself master of Syria, sent a colony to Samaria, and his generals took King Manasses, and carried him loaded with chains to Babylon. Asar-Addon died after a reign of 12 years.

ASAROTA, *asagura*, from *a* and *suru*, *I sweep*, a kind of painted pavements in use before the invention of mosaic work. The most celebrated was that at Pergamus, painted by Sesus, which exhibited the appearance of crumbs, as if the floor had not been swept after dinner; hence, according to Pliny, the denomination. Perrault supposes them to have been a black kind of pavements, of a spongy matter.

ASBESTOS. See MINERALOGY.

ASCALON, a town of Palestine, on the sea coast, 14 miles north of Gaza, and 30 south-west of Jerusalem. It was one of the satrapes of Egypt, and was noted during the crusades. It contains some precious remains of antiquity, long streets, and innumerable red granite pillars, mostly fallen. Long. 34. 47. E. Lat. 31. 38. N.

ASCANIUS, the son of Æneas and Crusa, succeeded his father in the kingdom of the Latins, and defeated Mezentius, king of the Tuscans, who had refused to conclude a peace with him. At length he founded Alba Longa, and died about 1139 years before the Christian era, after a reign of 38 years.

ASCENDANT, in *Astrology*, denotes the horoscope, or the degree of the ecliptic which rises upon the horizon at the time of the birth of any one. This is supposed to have an influence on the person's life and fortune, by giving him a bent and propensity to one thing more than another. In the celestial theme this is also called the *first house*, the *angle of the East*, or *Oriental angle*, and the *significator of life*. Such a planet ruled in his *ascendant*, Jupiter was in his *ascendant*, &c. Hence the word is also used in a moral sense for a certain superiority which one man has over another from some unknown cause.

ASCENSION, a solitary island, or rather rock, in the midst of the Atlantic, about 700 or 800 miles from the western coast of Africa. It was discovered in 1501 by Joao de Nova Gallego, a Portuguese navigator, who named it Ilha de Nossa Senhora de Conceição. It was seen a second time by Alfonso d'Albuquerque, in his voyage to India in 1503, and then received its present name. As-

Ass
||
Ascension

Ascension consists of a single rocky mountain, though shooting up into several detached peaks, of the most naked and desolate character, consisting in a great measure of volcanic remains. The beach, always beat upon by a heavy surf, is covered with a sand of snowy whiteness, which, when acted upon by the sun, is intolerable to the eyes. The sides of the cliffs consist of lava, variously coloured, and in different stages of decomposition. Easter Island and Terra del Fuego do not present a more dreary aspect. At a considerable height occurs a plain about eight miles in circumference, from the south-east quarter of which there rises a lofty hill, presenting an appearance of verdure not discoverable in any other part of the island. Here is found a grass peculiar to the island, and a few goats are fed, whose flesh is extremely delicate. Notwithstanding the unproductive character of this island, its excellent harbour, and the fish, sea-fowl, and turtle, with which it abounds, have made it a place of refreshment for the homeward-bound shipping. A crevice in one of the rocks has been employed for depositing letters, to be taken up by the next ship passing in a contrary direction, and has been hence called the sailor's post-office. Long. 14. 28. W. Lat. 8. 8. S.

ASCENSION DAY, a festival of the Christian church, held ten days before Whitsuntide, in memory of our Saviour's ascension into heaven after his resurrection.

ASCETERIUM, in ecclesiastical writers, is frequently used for a monastery, or place set apart for the exercise of virtue and religion. The word is formed from *ascetis*, exercise; or *ascetra*, one who performs exercise. Originally it signified a place where the athlete or gladiators performed their exercises.

ASCETIC, an ancient appellation given to such persons as, in the primitive times, devoted themselves more immediately to the exercises of piety and virtue in a retired life, and particularly to prayer, abstinence, and mortification. The word is derived from *ασκηω*, *exerceo*, I exercise. Afterwards, when the monks came in fashion, this title was bestowed upon them, especially upon such of them as lived in solitude.

ASCHAFFENBURG, a city in the Bavarian circle of the Lower Maine. It is situated on an elevation above the river Maine, containing eight churches, 755 houses, and 6590 inhabitants. The streets are narrow and crooked, the houses large and antique. Near it the castle, formerly the residence of the prince, is a fine building, with an orangery and pheasantry. There are several institutions for civil and ecclesiastical education. The trade consists in paper and leather made in the city, in building vessels to navigate the river, and in the transit commerce which the long stream creates.

ASCHAFFENBURG, a bailiwick in the circle of the Lower Maine, containing 10,635 inhabitants, in one market-town and 18 villages, besides several small hamlets. It lies on both sides of the Maine, is mountainous and woody, but produces good wine and cider, and feeds many herds of black cattle.

ASCHAM, ROGER, a very distinguished scholar and writer, was born at Kirby Wiske, a village in Yorkshire, near Northallerton, about the year 1515. John Ascham, his father, was house-steward in the family of Scroop, and by his wife, Margaret, was connected with several respectable families. A short time before his death, Sir Anthony Winfield, having conceived a predilection for his third son Roger, took him into his family, and extended his bounty so far as to give him the advantage of a private education along with his own sons. Under a domestic tutor he made a rapid progress in classical learning, and early discovered a great partiality for reading. The superiority of genius and docility of temper which he con-

stantly displayed induced his patron to send him to St John's College, Cambridge, in the year 1530.

The revival of Grecian and Roman literature at the period Ascham entered upon his studies was peculiarly favourable to the natural bent of his inclination. A desire of excelling uniformly influenced his conduct, and, adopting the maxim, *Qui docet, discit*, he began to teach boys the rudiments of the Greek language as soon as he was acquainted with the elementary parts himself. His plan was approved by Pember, and under the direction of this valuable friend he soon became acquainted with the best Greek and Latin authors. But he took particular delight in reading Cicero and Cæsar, and upon them formed the elegance of his Latin style, which proved so honourable and so advantageous in the after part of his life.

Ascham took his first degree of bachelor of arts in his 18th year, and was chosen fellow of the college about a month afterwards. The favourable disposition, however, which he manifested towards the reformed religion was no small obstacle in the way of his preferment. He was elected master of arts in the year 1537, and about this period he began to act in the capacity of a tutor.

His reputation for Greek learning soon brought him many pupils; and these were so well instructed that several of them afterwards rose to considerable eminence. Of these William Grindall was one of the most distinguished, who obtained the station of master of languages to the lady Elizabeth, upon the recommendation of Sir John Cheke. It appears uncertain why Ascham himself was not appointed to that honourable station; but his partiality for the university seems, from a hint in one of his letters, to have been the cause. At that period there was no particular chair appropriated to the Greek language, but Ascham was appointed by the university to read lectures upon that language in the schools. A dispute arose in the university at that time about the pronunciation of the Greek language, in which Ascham first opposed the method observed by Sir John Cheke and Sir Thomas Smith; but, upon more mature deliberation, he adopted that method, which has ever since been practised in the English schools. Both on account of the beauty of his handwriting, and the purity and elegance of his Latin, he was employed to write the public letters of the university.

By the advice of his friend Pember, he turned his attention to the study of instrumental music, and thereby enlivened his leisure hours, and prepared his mind for renewed exertion. In his study he also amused himself with embellishing the pages of his manuscripts with beautiful draughts, and in the field he joined in the diversion of the bow and arrow. The learned Ascham did not deem his labour improperly bestowed in writing a book entitled *Toxophilus*, in an age when the proper use of the bow was of more importance than for mere amusement. This work was written in a more natural, easy, and truly English diction than had hitherto been in use; and it also abounds with many beautiful allusions and curious fragments of English history. Ascham candidly acknowledges, that being anxious to make the tour of Italy, which was then the great republic of letters, and particularly of Grecian literature, he wished, by dedicating his book to the king, to obtain a pension, to enable him to make that tour. It reflects some lustre on the benevolence of Henry VIII. that in the year 1544 he settled upon him an annual pension of L.10, which Dr Johnson, considering the circumstances of the times, estimates at the value of L.100. Upon the death of Henry this pension was for some time discontinued; but it was again renewed by Edward VI., and doubled by Queen Mary. In the same year, also, Ascham obtained the ap-

Ascham.

Ascham. pointment of orator to the university; an office which he retained with great reputation during the period he was connected with the university.

For some years he received an annual gratuity from Lee, archbishop of York, but to what amount is not recorded; and, in 1548, upon the death of his pupil Grindall, preceptor to the lady Elizabeth, his pupils and writings had acquired him such celebrity, that he was appointed to direct the studies of that princess. He successfully acquitted himself in that honourable charge; but two years after, from some unknown cause of dissatisfaction, he returned to the university, having taken an abrupt leave of the princess. This part of his conduct did not lessen him in the esteem of Elizabeth; for in the same year she recalled him to court, and appointed him secretary to Sir Richard Morisine, ambassador to the emperor Charles V. In his way to London he paid a visit to Lady Jane Gray, whom he found in her chamber reading Plato's *Phædo*, in Greek, "and that," says he, "with as much delight as some gentlemen would read a merry tale in Boccace;" while the duke and duchess, and the rest of the household, were hunting in the park.

In the character of secretary to Sir Richard, besides aiding him in the management of his public affairs, he also conducted his private studies. During the mornings of four days in the week he read with him a portion of Herodotus or Demosthenes, and in the evenings some pages of Sophocles or Euripides; and on the other mornings he wrote the letters of public business, and on the evenings he either wrote his own private letters or continued his diary and remarks. While Ascham was on his travels, he made a short excursion to Italy; but was much disgusted with the manners of the people, especially of the Venetians. After his return from that tour, he favoured the world with a curious tract, entitled *A Report and Discourse of the Affairs and State of Germany*, &c.

Upon the death of Edward VI. Morisine was recalled, and Ascham returned to the university. But through the interest of Bishop Gardiner, the fortune of Ascham soon took a favourable turn, who, although he knew him to be a Protestant, obtained him the office of Latin secretary to the queen, with liberty to retain his university emoluments, and the additional salary of L.10 a-year. The prudence of Ascham enabled him to act a respectable part, both under the intolerant reign of Mary, and also in the most perilous situations during the reign of Elizabeth; and the readiness and elegance of his Latin style rendered him a useful member at court. He is reported to have written, during the course of three days, 47 letters to persons in the highest ranks of life.

When the crown passed to a Protestant prince, it made little alteration in the condition of Ascham, who still retained his station. He spent several hours every day in reading the learned languages with the queen, and her proficiency was equal to his labours; and it might have been expected that his rewards would have been more ample than L.20 per annum, together with the prebend of Westwang. Some have alleged that the queen kept him poor because he was addicted to cock-fighting, and in other respects extravagant; but the defects in his character should not have deprived him of the rewards due to actual services.

In consequence of a conversation which took place in the apartment of secretary Cecil, upon the subject of education, Sir Richard Sackville, who was present, requested him to write a book on the general subject of education. This work is entitled *The Schoolmaster*, and contains many excellent instructions to the teachers of youth. It was published by his widow after his death. By too close application to composing a poem, which he

intended to present to the queen on the new-year's day of 1569, he was seized with an illness which proved fatal, and died on the 23d of December 1568. His death was universally lamented, and the queen expressed her regret by saying, that "she would rather have lost L.10,000 than her tutor Ascham." His epistles, which are valuable both on account of their style and historical information, were published after his death, and dedicated to the queen: the best edition is that of Mr Elstob, published at Oxford in 1703. His English works were published in 4to, with a life by Dr Johnson, in 1767. This edition has been reprinted in 8vo.

ASCHELDORF, a bailiwick in the circle of Meppen and province of Osnaburg, in the kingdom of Hanover. It lies on the banks of the Ems, and contains two towns and five villages, with 8972 inhabitants, almost wholly Catholics, with many remains of old German habits and prejudices.—The capital of the bailiwick is of the same name, and contains one church, a monastery of Franciscans, and 1177 inhabitants, several of whom are seamen.

ASCHERSLEBEN, a circle in the government of Magdeburg and province of Saxony, in Prussia, formed out of a part of the principality of Halderstadt and the abbey of Quedlinburg. It contains 198 square miles, or 126,720 acres. The population in 1817 amounted to 36,283 persons. The Bode and the Eine are the chief rivers; and on their banks the land is highly fertile, producing great crops of corn, flax, and rape-seed. The city of Quedlinburg is the chief place of the circle.

ASCHERSLEBEN, a city in the circle of the same name, containing 1178 houses and 8731 inhabitants. It has an extensive trade in friezes, flannels, and other woollen goods, and in linen, leather, tobacco, and rape-oil.

ASCI, among geographers, an appellation given to those inhabitants of the earth who at certain seasons of the year have no shadow: such are all the inhabitants of the torrid zone when the sun is vertical to them.

ASCITÆ (from *ασκος*, a bag or bottle), in *Antiquity*, a sect or branch of Montanists, who appeared in the second century. They were so called because they introduced a kind of Bacchanals into their assemblies, who danced round a skin or bag blown up, saying they were those new bottles filled with new wine whereof our Saviour makes mention, Matth. ix. 17. They are sometimes also called *Ascodrogita*.

ASCLEPIA, a festival of Æsculapius, the god of physic, observed particularly at Epidaurus, where it was attended with a contest between the poets and musicians, whence it was likewise called *Ἱερος Ἀγών*, the sacred contention.

ASCLEPIAD, in ancient poetry, a verse composed of four feet, the first of which is a spondee, the second a choriambus, and the last two dactyls; or of four feet and a cæsure, the first a spondee, the second a dactyl, after which comes the cæsure, then the two dactyls; as, *Mæcenas atavis edite regibus*.

ASCLEPIADES, one of the most celebrated physicians among the ancients, was a native of Prusa in Bithynia, and practised physic at Rome under Pompey 96 years before the Christian era. He was the head of a new sect; and, by making use of wine and cold water in the cure of the sick, acquired a very great reputation. He wrote several books, which are frequently mentioned by Galen, Celsus, and Pliny; but they do not now exist.

ASCLEPIADES, a famous physician under Adrian, of the same city with the former. He wrote several books concerning the composition of medicines, both internal and external.

ASCODUTÆ, in *Antiquity*, a sect of heretics in the second century, who rejected all use of symbols and sacraments, on this principle, that incorporeal things can-

Aschen-
dorf
||
Ascodute

not be communicated by things corporeal, nor divine mysteries by any thing visible.

ASCOLI, one of the delegations into which the Papal States in Italy are divided. It comprises a part of the ancient mark of Ancona or of Fermo. It is bounded on the north-west and north by Fermo, on the east by the Adriatic Sea, on the south by the territory of Naples, and on the west by Spoleto. The extent is 480 square miles, or 307,200 acres. The Appennines are in part included in this province. It contains 3 cities, 4 market-towns, and 44 villages, with 69,058 inhabitants. The soil is generally fruitful, and the climate salubrious.—The capital of the delegation is of the same name, the see of a bishop, and the tribunal of law. It is situated at the junction of the river Castellano with the Tronto. In the mouth of the latter is a small harbour for coasting vessels. The city contains a cathedral, 12 parish churches, 12 monasteries, 6 nunneries, a Jesuit's college, and 7550 inhabitants. Long. 13. 28. 25. E. Lat. 42. 51. N.

ASCOLIA, in *Grecian Antiquity*, a festival celebrated by the Athenian husbandmen in honour of Bacchus, to whom they sacrificed a he-goat, because it destroys the vines; and, to show the greater indignity to an animal hated by Bacchus, the peasants, after having killed him, made a foot-ball of his skin.

ASCRIPITII, or ADSCRIPITII, a kind of serfs, so annexed to the lands that they may be transferred and sold with them. Adscriptitii is sometimes also used in speaking of aliens or foreigners newly admitted to the freedom of a city or country.

ASDRUBAL, the name of several Carthaginian generals. See CARTHAGE.

ASHANTEE, a country in Western Africa, situated in the interior of that part of Guinea called the Gold Coast. It forms now the most powerful of all the kingdoms in that quarter of Africa, and is perhaps the most improved of any among the completely native states which have remained strangers to the Arabic language and Moslem institutions. This kingdom, therefore, possesses now a somewhat peculiar interest, and may deserve to be treated of at some length.

The Ashantee empire, including the numerous districts, once independent, but now entirely reduced under its control and jurisdiction, is considered by M. Dupuis as extending from 5. 0. to 9. 0. N. lat., and from 0. to 4. 0. W. long., and may thus comprise a space of about 50,000 square miles, inhabited by 3,000,000 of people. The original Ashantee, however, occupied by the nation who have subjugated this large extent of territory, is not supposed to include more than a third of this large space, nor to have a population exceeding 1,000,000.

Tradition represents the Ashantees as deriving their origin from numerous bands of emigrants, who, two or three centuries ago, were driven before the Moslem tribes migrating southward from the countries on the Niger and Senegal. The Ashantees having occupied and cleared a region before covered with almost impenetrable forests, defended themselves with a valour which became part of their national character, and which raised them from a band of fugitives to the rank of a powerful and conquering nation. They even subdued and reduced into vassalage several of the Moslem tribes by whom they had been formerly supplanted.

Early in the 18th century the Ashantees first came under the notice of Europeans through the wars in which they engaged with the kingdoms bordering on the maritime territory. Among these, Dinkira is described by Bosman as holding such a pre-eminence in wealth and power, that it looked down with contempt on all the surrounding tribes. Yet Sai Tooto, the king of Ashantee,

emboldened by successive conquests, and by the tried valour of his people, hesitated not to encounter this formidable potentate. The war was excited by an insult offered to a member of an embassy sent by the king of Ashantee, consisting, according to a usage prevalent in this part of Africa, of a detachment of his numerous wives. The pride of Dinkira caused its sovereign to refuse all explanation or atonement; and war immediately ensued upon a great scale, each party mustering their allies and tributaries; and successive battles were fought with such fury, that 100,000 men were reported to have fallen on each side. It terminated in the complete overthrow of Dinkira, which had its pride completely humbled, and has continued ever since a mere vassal and tributary of Ashantee.

Sai Tooto may be considered as the real founder of the power of this kingdom. He either built or greatly extended and embellished Coomassie, the capital; he subdued the Mahometan countries of Gaman and Banna, the latter of which has been called the right arm of Ashantee; and he extended the empire by conquests both on the east and west. But it remained still quite an inland state, nowhere approaching the coast nearer than 40 or 50 miles. Finally, Sai Tooto having invaded the country of Akim, when marching at the head of a small detachment to join his army, was surprised and slain. The Ashantees, who held that prince in the highest veneration on account of his justice and valour, were so deeply affected by this catastrophe, that they have ever since distinguished the day by terms expressive of its gloomy character—as the dreadful day—the day of God's chastisement. In fact, it was followed by a temporary anarchy, and by contests for the succession, which encouraged all the vassal kingdoms to throw off the yoke; so that when Sai Apoko in 1731 came into full possession of the throne, the conquests of his predecessor were to be made afresh. However, he did make them: Gaman, Assin, Akim, and Dinkira, were by new victories annexed to the empire more firmly than before, while farther acquisitions gradually opened his way to the coast. Sai Apoko, in the latter part of his reign, involved the kingdom in violent agitation by an attempt to deprive the nobles of their rights and privileges. This gave rise to a serious rebellion, which the king, indeed, triumphantly suppressed; yet on his death, which happened soon after, the chiefs, before raising his successor to the throne, were careful to abrogate these innovations, and regain their wonted share in the administration.

Sai Akwasy, the next sovereign, was chiefly employed in suppressing insurrections which continually arose among the numerous little subject tribes, amounting, it is said, to forty-seven, held in reluctant subjection to his government, and who seized every opportunity to shake off the yoke. The contest with Gaman was waged with various and long doubtful success, but at length it was triumphant. In an attempt, however, to cross the Volta and invade Dahomy, he encountered a complete overthrow; and Ashantee has never again ventured to extend her ambitious views to that fierce and warlike kingdom.

The reigns of Sai Quamina and Sai Apoko II. were not distinguished by any events of great magnitude. In 1800 the throne was mounted by Sai Tooto Quamina, who soon showed himself animated by a peculiar spirit of enterprise and ambition. He appears early to have formed a desire of opening a communication with white nations, and of improving his country by the introduction of their arts and knowledge. Occupied, however, by wars in the countries to the north, and by an insurrection in Gaman, he could not for some time turn his views in that direction. About 1808, however, a dispute arose among the chiefs

Ashantee. of Assin, which the king seems to have made very great efforts to compose in a friendly manner; but, through the violence and rashness of the Assinese, it ended in an open rupture. The insurgent forces were defeated with great slaughter, and the chiefs compelled to seek refuge on the coast among the Fantees, there the ruling people. The king again made overtures of accommodation; but by a strange infatuation the rebel chiefs not only rejected these, but put his messengers to death with every species of outrage. The Ashantee monarch then threw away every remnant of forbearance, and determined that every thing most dreadful in African warfare should be felt by them, and by the Fantees their protectors. The allies found themselves wholly unable to resist the torrent of invasion; the country was laid waste with fire and sword, and they were driven with dreadful slaughter towards the coast. At length the fugitives reached the town of Anamaboe, where there was then a British fort. The governor exhorted the Anamaboes to endeavour to make pacific arrangements with this powerful enemy, and offered his mediation; but the citizens, falsely confident in their own strength, resolved to abide the contest. When a division, however, of the Ashantee army had destroyed the neighbouring town of Cormantine, the inhabitants of which came flying to Anamaboe for refuge, the governor contrived to open a communication with the king, requesting to know the cause of his attacking Anamaboe, and offering to mediate an accommodation. The reply was, that on sending 20 barrels of gunpowder and 100 muskets, the English would be made acquainted with the king's intentions. This reply afforded no opening to negotiation; and in fact they learned that the Ashantee chief, on reaching the sea, had shown an extraordinary exultation, having three times dipped his sword into the water. A reconnoitring party, which the enemy in the first instance sent forward, was repulsed, after a hard contest, by the Anamaboes; but on the following day, when the whole force of the invader was brought up, the citizens were seen retreating in the utmost disorder. They found no refuge even in the town, to which they retreated, but were pursued with the most dreadful slaughter to the margin of the sea. The English governor, after receiving into the fort as many of the old men, women, and children, as its walls could contain, vainly endeavoured to repel the enemy by continued discharges of musketry and grape shot. The attempt was fruitless; and after having completely destroyed the town, they advanced against the castle, and made the most desperate efforts to carry it by storm. The situation of the English was critical in the extreme: to oppose a force estimated at 15,000 they had not above 24 men, several of whom were artificers and free mulattoes. The Ashantees continued the attack for several hours, firing with such precision as to cut off every man who appeared at an embrasure, and the garrison was reduced to eight men fit for service. Towards evening, however, the enemy, having been unable to gain an entrance at any point, desisted. Next morning the scene around the fort displayed a dreadful picture of the ravages of barbarous warfare; the houses of the city mostly unroofed or on fire; the shore strewn with numerous dead bodies, against which the waves were dashing; the piteous cries of the women and children who had found refuge within the fort. The enemy, however, showed no haste to renew the attack; and in the afternoon a reinforcement of four officers and twelve men was landed from Cape Coast. The governor then, in pursuance of directions from the commander-in-chief, hoisted a white flag in sign of amnesty, which was received cordially, and even with joyful acclamations. The two soldiers who bore the flag were welcomed and presented with a fat sheep; but it appeared

that nothing final could be concluded without a meeting between the king and the chief governor, in which view every effort was used to induce the king to pay a visit to Cape Coast Castle; but he very naturally declined to place himself in the power of those with whom he had just waged so deadly a warfare. Colonel Torrance, the chief governor, then repaired to Anamaboe, and forming a procession as handsome as his numbers admitted, went out and waited on the monarch. The English were dazzled by the splendour and dignity displayed by the retinue of the Ashantee prince, which greatly surpassed all that they had observed on the coast. The great men wore dresses of rich silk, and their swords, axes, flutes, and other instruments, were either of solid gold or profusely adorned with that precious metal. The court etiquette was studied and dignified; each of the great officers gave separate audience, seated under a huge umbrella, and surrounded by numerous attendants. The king, of a deep black complexion, was well formed, with an open and pleasing countenance: he wore a plain silk dress, without any of the golden ornaments with which the inferior captains were loaded. A treaty was concluded, which could not but be satisfactory to the monarch, since, according to M. Dupuis, it included a complete acknowledgment on the part of the governor, that the whole territory of Fantee, including Cape Coast itself, the capital, belonged by right of conquest to the Ashantee empire. The governor took a still more questionable mode of securing the favour of this great potentate. Cheboo and Apoutay, the chiefs with whom this dreadful war originated, had fled to Cape Coast, where they lived under at least the tacit protection of the British government. Now, however, parties were despatched to attack them, who seized Cheboo after a desperate resistance; but Apoutay, beating off the assailants, effected his escape. The former chief was then delivered as a propitiatory offering to the king, by whom he was put to death with cruelty and ignominy.

Although the Ashantees carried all before them in the field, an epidemical disorder, causing a considerable mortality in their army, obliged them to retire. Then the Fantees, according to their usual rash and imprudent course of proceeding, threw off the yoke. This brought down upon them, in 1811, a second expedition, in which the invader met with equal success, and for some time carried all before him; but one of those internal rebellions to which the kingdom was always subject interrupted his career, and obliged him to return. The Fantees, always courageous in the absence of danger, again reared their heads, and prepared for themselves, in 1816, an invasion more formidable than either of the two preceding. They suffered a most disastrous overthrow; Cape Coast was held in long blockade, and the Fantees were finally compelled to own themselves the subjects of the king of Ashantee.

The British government, actuated by very enlightened views, felt a wish to cultivate the alliance of this great African potentate, and to open a direct communication with him. They thus hoped not only to secure his friendship and commerce with his territories, but to obtain extensive information respecting the interior of Africa. In 1817, Messrs James, Bowdich, and Hutchison, departed on a mission to Coomassie. They had to penetrate through a country, great part of which was overgrown with dense and entangled woods, the route through which consisted only of a narrow and difficult footpath. These obstacles, joined to an illness with which Mr James was attacked, caused the journey, though extending not more than 100 miles, to employ nearly a month. On their arrival they were considerably dazzled both by the extent and handsome appearance of the city, compared with the

Negotiations and war with the English.

Ashantee. maritime capitals, and also by the wild and brilliant array of the caboceers or great war-chiefs. They were soon introduced to the king, whom they found still more profusely loaded with embellishments, consisting of golden ornaments, beads, and amulets. Yet the strings of human teeth, and the executioner seated with his hatchet on his breast, and his stool clotted with blood, threw into the scene a character truly savage. The monarch received them, however, with that dignified politeness which, unless when overcome by passion, he always studiously maintained. He invited them to the market-place, and gave them a public audience in presence of the chiefs and people. The presents, which consisted chiefly of ornamental fabrics of British manufacture, excited his highest admiration: he carefully, and with an intelligent eye, examined their structure. After one or two of these harmonious interviews, subjects of business came under discussion. The king introduced the subject of certain sums which the British were bound to pay to the native governments, for permission to hold fortified factories; making in a manner the ground-rent of their castles. These sums the Fantees, as the ruling people on the coast, had been accustomed to receive; but the king, as having conquered the whole Fantee territory, claimed them now as due to himself. According to the ideas established in Africa, and indeed to the ordinary rights of conquest, the demand seems to have been legitimate. There had, however, been some misunderstanding: Mr James came unprovided with any instructions to meet this claim, and simply replied that he would refer for instructions to the government at Cape Coast Castle. This appears to have been quite foreign to the understanding and expectations of the monarch, who conceived that they came, as he said, "to make peace and settle all palavers." On finding them wholly unprepared to enter on what he viewed as the main object of discussion, he considered himself insulted; that contempt was thrown upon him, and a determination manifested for war. In vain did Mr James protest that they wished only peace and trade: his passion became always more furious; he called them cheats and liars, then started from his seat, bit his beard, exclaiming, that had a negro brought such a message he would have cut off his head. On seeing matters come to this extremity, the two junior members of the mission, Messrs Bowdich and Hutchison, formed a resolution certainly very imprudent and contrary to diplomatic rule. Conceiving that Mr James, by blind and obstinate adherence to rule, was endangering the English interests, and perhaps even the safety of the mission, they took upon themselves to supersede him, and assume the negotiation into their own hands. They conducted it in a manner altogether satisfactory to the king: a treaty was concluded, by which all his demands were granted; and, after a residence of several months, in which they were perfectly well treated, they returned to Cape Coast.

The government at home, though they demurred somewhat to the very irregular course followed by Mr Bowdich and his companion, saw evidently the wisdom of cultivating an intercourse with this powerful African court. They determined to station at his court a fixed resident, and nominated to that station M. Dupuis, who had long filled with credit the important post of British consul at Mogadore. M. Dupuis was sent out with instructions to cultivate to the utmost of his power the friendship of this potent monarch, to promote trade with his dominions, and to open through them an intercourse with the interior.

The new consul, being detained in England by various circumstances, did not arrive at Cape Coast till January 1819. By that time a complete and unfortunate change

had taken place in the views of the British local government. They had been gained entirely over to the interest of the Fantees or coast natives, who were constantly on the spot, and possessed eloquence, talents, and address. An insurrection had arisen in the interior of the Ashantee monarchy, respecting which the most exaggerated rumours were spread and listened to with blind credulity. Insulting messages were sent to the king, who was also informed that the natives of Cape Coast were setting his authority at open defiance, and were forming a wall to defend the town. The Fantees, so recently subjected, could not be blamed for endeavouring to procure their own emancipation; but the English, who had so much experience of their weakness, ought by no means to have committed themselves in the quarrel. Under the views which he had formed, however, the governor, on various pretences, prevented M. Dupuis from proceeding on his mission. Yet, while this rash and confident spirit continued in full force, rumours of a very opposite description began to arise, and became so prevalent, that the boldest adherents of the present policy were struck with apprehension. It was now confidently stated that the king had gained a complete victory over the rebels; nay, it began to be rumoured that he was in full march with an army upon Cape Coast. That prince, however, appears to have shown a very considerable disposition to effect an amicable adjustment of differences. A messenger of high rank arrived at the castle, and having produced a little Morocco trunk, drew from it the treaty, which was read over, article by article, and repeated appeals made to the governor on the manner in which it had been violated. He was unable to deny the charges; and the confusion which he could not avoid feeling, with the generally changed aspect of affairs, induced him to assume a much more moderate tone. M. Dupuis was even introduced, and his mission mentioned, with which the messenger seemed much pleased, though he could not, without some special instructions, give him an invitation to proceed to Coomassie. Soon after, an ambassador of much higher rank was announced, and excited a stronger sensation, it being reported that he brought with him an army to enforce compliance. His appearance, however, dissipated these apprehensions: he brought with him indeed a train of twelve hundred persons, but these were partly women and boys; and the assemblage was evidently one of state, not of war. The ambassador, however, brought the ultimatum of the king as to atonement demanded for the breach of fealty committed by the people of the town, and in which they had been supported by the English. After enumerating all the wrongs of which they had been guilty towards his sovereign, he demanded the sum of 1600 ounces of gold from the town, and the same amount from the governor. This last demand was rejected as wholly inadmissible, though there was not the same objection made to equitable compensation being required from the natives. It being then found that the ambassador had brought a welcome to M. Dupuis, the governor, in these urgent circumstances, deemed it wisest to withdraw the interdict hitherto placed upon that gentleman's proceeding to Coomassie, and to place in his hands the task of obtaining the best possible terms from this powerful monarch.

M. Dupuis set out on the 9th February 1820, and on the 28th arrived at Coomassie. He soon obtained a public audience of the king, who received him with dignified politeness. After a few days spent in pompous and unmeaning ceremonies, more confidential meetings took place, and business was entered upon at full length. The king expressed uniformly the utmost indignation at the attempt of the natives to shake off his authority. On one occasion

Ashantee.

Ashantee. when he happened to be in peculiarly bad humour, this broke out in a demeanour partaking almost of madness. Raising his voice to its utmost pitch, and assuming a countenance of demoniacal frenzy, he threw himself convulsively back in his chair, clenched his fists, and stretched out his arms and legs, while he bellowed out the most direful imprecations against the natives of Cape Coast, not even excepting those present. The foam all the while flowed down his beard in copious discharges, and the saliva spouted from his mouth upon all around him. He even vociferated, "White men come to my country to trade,—what have they to do with my slaves? *Smitty* (Governor Smith) cheats, and joins the Fantees. The Cape Coast people ought to die. Let me go there, let me have the jaw-bones of Aggry and Deljraaf. I don't want their gold; I want the blood of bad men to wash my stool." Afterwards, however, he made a sort of apology for this violent sally, and in his calmer moods was found reasonable and even conciliatory. He expressed great dissatisfaction with the governor of Cape Coast, but the highest respect for the king, whom he seems even in some degree to have owned as a superior, and called him, of course in mere courtesy, his master; only saying, "for the *blacks*, I am king, and I will be paid or I will kill them." M. Dupuis seems to have proceeded very judiciously, and in a manner at once firm and courteous. The king occasionally showed suspicions of his acting as a spy, and even threw out hints to that effect, with many apologies, however, and representing the idea as having originated with his nobles and chiefs. He seems in general to have been fully convinced of the candour and good faith of the English envoy, who, on his side, recognized fully the monarch's claim to the entire sovereignty of the Gold Coast, including the ground on which the forts stood. This implied the validity of the *notes* of rent, amounting for each to the mighty sum of L.8 a month, which threatened to involve Africa in warfare. The king again dropt entirely the large payment demanded from the governor; and, admitting the plea of their poverty, greatly reduced his requisition from the natives. He agreed likewise that the English should exercise a certain jurisdiction in the immediate vicinity of their forts, even over such of his own subjects as should happen to reside there. Upon these principles, a treaty was drawn up, which adjusted satisfactorily all the differences between the two parties. The king dismissed M. Dupuis with many marks of esteem and kindness, sending along with him two natives of distinction, to proceed as ambassadors to England, with a present of two beautiful leopards.

M. Dupuis now returned to Cape Coast with the agreeable impression of having brought this important and difficult negotiation to a fortunate issue. He was deeply disappointed when the governor altogether disowned the treaty, representing it as having betrayed British interests, and as having wantonly transferred to Ashantee the sovereignty of the Gold Coast. At the same time the Fantee party persuaded Sir George Collier to refuse transporting to Britain the ambassadors sent by the king of Ashantee; a conduct which could not but be in the highest degree offensive to that monarch.

M. Dupuis returned to England to represent the particulars to the government; but an entire change meantime took place in the administration of the British affairs in Africa. The African Company were induced to resign the command hitherto held by them over the forts, which were taken entirely into the hands of the crown. The first step adopted in consequence, was to invest Sir Charles M'Carthy with the general government of all this range of coast. The king of Ashantee, though highly indignant at the conduct of the former governor, on learning this

alteration, seems to have paused, in hopes of its bringing more conciliatory counsels. The new governor arrived early in 1822; but though he had communicated with M. Dupuis, who earnestly endeavoured to impress him with his own ideas of African politics, Sir Charles soon implicitly adopted the principles and policy of the Fantee natives. He placed the town in a posture of defence, and formed alliances with all the neighbouring tribes, who ranged themselves under his standard. Nothing was heard of the former dreaded conqueror of the Gold Coast, who, it was hoped, had been overawed by the formidable force which the English exhibited. In fact, however, he was busied in preparations of various kinds, collecting troops, making incantations, and determining the lucky or unlucky times of commencing the campaign. At length a negro serjeant in the English service was seized in the great square of Anamaboe, on pretext of some injurious expressions respecting the king; and after being detained for six weeks, seemingly in expectation of some negotiation being opened for his release, was beheaded at Denqua. The king then commenced open war, summoning all his vassal princes, and calling upon them "to arm against Britain, to the very fishes of the sea." To Sir Charles he sent notice that his scull would soon adorn the great war-drum of Ashantee. Yet at this very time he made overtures through the Dutch government at Elmina, who had always prudently cultivated his alliance. Messengers sent by each party met at Elmina, and a speech was made on the king's part, when he presented indeed a most formidable list of grievances, yet showed himself willing to impute these to the Fantees and the people of Cape Coast rather than to the English; but this discourse was deemed unworthy of answer.

It behoved now the English to meet in the field the formidable enemy whom they had provoked, and taken no pains to appease. Captain Laing having been sent forward with a reconnoitring detachment, encountered an advanced corps of the enemy and totally defeated it; an exploit which increased the rash confidence now prevalent among the British and their allies. The force which could be depended upon, though small, and consisting in a great measure of the merchants and civil servants of the colony, was imprudently divided. Besides Mr Laing's detachment, the main body was split into two parties, under Sir Charles M'Carthy and Major Chisholm. The former, commanding about 1000 Europeans, was attacked near the boundary stream of the Bossem Pra, by a force of the enemy amounting to 10,000. The English fought for some time with great bravery, till their ammunition failed, when Sir Charles commenced his retreat; but the enemy then succeeded in throwing a large corps on his rear, and thus causing a total and destructive route. Only 50 men, including two officers, Major Ricketts and Lieutenant Erskine, returned to the castle. All the rest, among whom were the chief civil functionaries, paid the penalty of their rash counsels. Respecting their fate, there is only the fatal alternative, that they either fell on the field or perished amid tortures inflicted by this barbarous enemy. The former and milder lot, according to the most probable account, befel Sir Charles, though his bones were carried as a trophy to Coomassie.

The Ashantee army now marched upon Cape Coast, laying waste the country with fire and sword. At that place, however, the detachments of Major Chisholm and Captain Laing had united with the wrecks of the main corps, and prepared for defence with the characteristic vigour and courage of English troops. The king, flushed with victory, made repeated and desperate assaults, but was on each occasion repulsed with great loss; and sickness having made its way into his camp, he at length

Ashante. broke up and retired to Coomassie. It was supposed that he withdrew only to collect a more formidable force, and renew the invasion. Such a design was frustrated by internal disturbances; and the English having since greatly limited their connection with the Gold Coast, and even withdrawn their garrisons from all the forts except the one at Cape Coast, and having also wisely adopted a more conciliatory policy, the good understanding between the two powers has been happily restored. There is even, we believe, at present, a British resident at Coomassie.

Present state of Ashante. Ashantee proper, comprising about 14,000 square miles, and a million of inhabitants, presents a dense and almost impenetrable forest, the routes through which consist merely of narrow winding tracts, in which, though it is possible for a man to ride, or a palanquin to be carried, no waggon of any description could pass. The interior country round the towns, however, is cultivated with diligence, the fields being kept very clean, and yielding in abundance grain, yams, vegetables, and fruits. The territory yields also a considerable quantity of gold; and that precious metal is brought in still greater abundance from the regions farther to the north, particularly Gaman, where it occurs not merely in the usual form of gold dust, but in pretty large fragments, mingled in pits with rock and gravel. It is even said that, but for a superstitious idea, which induces the natives to leave the largest deposits untouched, the produce might be much more ample. The Ashantees are skilful in several manufactures, particularly in the great African fabric of cotton, which they weave with a loom differing little from that of Europe. Their pottery and works in gold are also skilful, though surpassed by those produced in the more southern countries.

The government of Ashantee forms a mixture of monarchy with a military aristocracy; the lower orders being held in the most complete thralldom, and liable either to be put to death or sold into slavery at the will of the chiefs. The king carries on all the ordinary administration of the state; but in questions relating to peace or war he is bound to consult the council of the caboceers or captains, which M. Dupuis calls a senate. Each of these caboceers keeps a little court, where he gives audience, and makes a profuse display of barbarous pomp. They wear rich silken robes, curiously interwoven with variously coloured threads; and the most common domestic utensils are of solid gold. Leopards' skins, red shells, elephants' tails, eagle and ostrich feathers, are intermingled with Moorish charms and amulets, and with strings of human teeth and bones. Polygamy is indulged to the most enormous extent. The king has a regular allowance of 3333 wives; but in Africa these princesses are employed variously, as guards, messengers, and even in the humblest services. The crown, as often happens in barbarous countries, descends to the king's sister's son, not to his own offspring.

The Ashantee monarchs, though so extremely ambitious, appear to pay considerable regard to the faith of treaties, seeking always a plausible ground of war; and, even when justly provoked, not usually commencing it without previous overtures of negotiation. The barbarous and capricious governments, however, by which they are surrounded, jealous of the Ashantee power, without duly measuring their own strength, afford frequent cause of justifiable invasion. Thus, during the last century the Ashantees have conquered Dinkira, Aquamboe, Aquapim, and Assin, countries which lay between them and the coast, and held the chief sway there on the first arrival of Europeans. Then they reduced the whole of the Gold Coast. During the same period, towards the north and the interior of Africa, they subdued the territories of Gaman, Banna, Tonouma, and Degomba, inhabited chiefly by

Moslems, before whom the Ashantees had been at first compelled to recede; but notwithstanding the enmity thus naturally generated, the conquerors wisely extended their full protection to the professors of this faith, and raised them often to equal favour and honour with the natives. The king even had made them believe that he felt some disposition to embrace their faith.

The darkest feature in the Ashantee character undoubtedly consists in the system of human sacrifice, carried to a truly dreadful extent. It is founded on a wild idea of filial and relative piety, which makes the chiefs fancy it their duty to water with blood the graves of their ancestors, whose rank in the future world will, they imagine, be measured by the number of attendants thus sent along with them. There are two fixed annual periods called the great and little *Adai customs*, at each of which human victims are immolated to a monstrous extent. Still more dreadful is the custom celebrated after the death of the king, or any member of the royal house. When Mr Bowdich was at Coomassie, the monarch, in honour of his mother, had sacrificed no less than 3000 victims. They are chiefly prisoners of war or condemned criminals. The nobility also vie with each other on these occasions in testifying respect by the number whom they immolate; they often rush out, seize the passenger of humble birth, and drag him in for this fatal purpose. Hence, during this awful period, the citizens of Coomassie shut themselves up in their houses, or, if compelled by necessity to go abroad, fly along the streets with trembling speed, every moment in fear of becoming victims to this cruel superstition.

There appears to prevail at this court a very considerable desire to introduce a higher degree of civilization, and to raise the Ashantees in the scale of nations. Conscious of the superiority of Europeans, the monarch shows a peculiar ambition to assimilate his system with theirs. From the first he was anxious to cultivate a connection with the English; and M. Dupuis found him impressed with the most lofty ideas of the power and magnificence of king George. He was then employed in erecting a palace in the European style, under the direction of Dutch architects from Elmina. His subjects were very unskilful in this task, but, by numbers and by loud cries, they endeavoured to compensate for the deficiency of skill: they suggested to Dupuis the odd idea of "a legion of demons attempting in mockery a Babel of modern invention." The interior was meant to be splendidly adorned with gold and ivory; and the king said on another occasion, "I must have every thing suitable, and live like a white king." Perhaps, indeed, there is no quarter where the views entertained for the civilization of Africa could be prosecuted with a fairer chance of success. The people of free barbarous states are turbulent, intractable, attached to their former rude and irregular habits, compared to the indulgence of which a few external accommodations are regarded with great indifference. It is otherwise with an absolute monarch, who, when once inspired with a desire for the refinements and enjoyments of civilization, can enforce their production by the ministry of others, and may thus, in gratifying his own ambition, rapidly introduce among his subjects the elements of improvement and industry. (F.)

ASH-WEDNESDAY, the first day of Lent, supposed to have been so called from a custom in the church, of sprinkling ashes that day on the heads of penitents then admitted to penance.

ASHBOURN, a market-town in the hundred of Wirksworth, and county of Derby. It is 139 miles from London, on the high road to the north-west part of the island. It stands on the small beautiful river Dove, by which

Ashantee
||
Ashbourn.

Ashburton stream some mills for spinning cotton are turned. There is a good corn market held every Saturday. The population was, in 1801, 2006; in 1811, 2112; and in 1821, 2188; but the parish of Ashbourn is more extensive than the town, and at the last census contained 4708 inhabitants.

ASHBURTON, a market and borough-town in the hundred of Teignbridge, and county of Devon, 191 miles from London and 19 from Exeter. It stands in a valley surrounded on every side by hills, on the great road to Plymouth. The parish-church is in the cathedral form, with a lofty tower and spire. It is one of the four towns in which a court is held for the mining districts. There was formerly an extensive trade in the manufacture of serges, which has declined much of late years. It is an ancient borough, returning two members to Parliament, who are chosen by the freeholders, in number about 200. The market is held on Saturday. The population was, in 1801, 3080; in 1811, 3058; and in 1821, 3403.

ASHBY DE LA ZOUCH, a market-town in the hundred of West Goscote, of the county of Leicester. It is in a fine valley on the borders of Derbyshire, on the river Gilweskaw, and surrounded by a most fertile district. The town is well built. Near it is an ancient castle belonging to the Earls of Huntingdon, and a mineral spring, increasing in celebrity, called Griffydam. There is a large market every Saturday. Population in 1801, 2674; in 1811, 3114; and in 1821, 3403.

ASHES, the fixed residue of combustible substances which remains after they have been burnt.

Several religious ceremonies depend upon the use of ashes. St Jerome relates that the Jews in his time rolled themselves in ashes as a sign of mourning. To repent in sackcloth and ashes is a frequent expression in Scripture for mourning and being afflicted for our sins. A heifer being sacrificed upon the great day of expiation, its ashes were distributed among the people, who made from them a sort of lustral water, which they used in purifications, by sprinkling it on such persons as had defiled themselves by touching a dead body or being present at a funeral (Numb. xix. 17).

The ancient Persians had a sort of punishment for some great criminals, which consisted in executing them in ashles. The criminal was thrown headlong from a tower 50 cubits high, which was filled with ashes to a particular height (2 Macc. xiii. 5, 6). The motion which he used to disengage himself from this place plunged him still deeper into it, and this agitation was further increased by a wheel which stirred the ashes continually about until he was stifled.

ASHFORD, a town in the hundred of Chart, in the county of Kent. It has a market on Tuesday. It is 57 miles from London and 12 from Canterbury, in a district of great fertility, watered by the rivers Esk and Stour. The church is a fine old Gothic edifice, containing a monument to a countess of Athol more than 400 years old. The population was, in 1801, 2151; in 1811, 2532; and in 1821, 2773.

ASHLAR, a term used among builders, by which they mean common or free stones, as they come out of the quarry, of different lengths and thicknesses.

ASHLERING, among builders, signifies quartering, to lath to, in garrets, about two and a half or three feet high, perpendicular to the floor, up to the under side of the rafters.

ASHMOLE, ELIAS, an industrious English antiquary and philosopher of the 17th century, was born at Lichfield in 1617. Having enjoyed the advantages of a country education, he went to London at the age of 16, and resided in the family of James Paget, Esq. one of the barons of the exchequer, and then turned his attention to

the law and various branches of literature. In the year 1638 he married, and commenced the business of attorney in London. When the civil war began, he, being then a widower, entered into the king's service in the ordnance department. When residing in the city of Oxford in that capacity, he entered Brazen Nose College, and began the study of natural philosophy, mathematics, and astronomy. Naturally inclined to grave and scientific trifles, he wandered too far into the wilds of astrological imposture, not a little encouraged by several eminent men of that age. From the same cause he entered keenly into the secrets of masonry, and made considerable additions to the history of that sect.

When Worcester was surrendered to the parliament in 1646, Ashmole retired to London, where he became acquainted with the famous astrologers, Moore, Lilly, and Booker. Having removed to Berkshire in the year following, he added the knowledge of botany to his other acquisitions. There he became acquainted with lady Mainwaring, a well-jointed widow, whom he married in 1649; and although her estate was sequestrated on account of his loyalty, yet through the interest of Lilly and others he again recovered it, and afterwards settled in London, where his house became the resort of all the curious literati. A taste for chemistry, or rather alchemy, was produced, by his conversation with William Blackhouse; and Ashmole, under a feigned name, published a work upon that subject. The next effort of his industry was a collection of the manuscripts of English alchemy, which he published under the title of *Theatrum Chymicum Britannicum*, in 4to. This work was the effect of great labour and expense; and although it procured him much fame among the learned, yet it was only a collection of *Alchemy*,—he appears to have been ignorant of real chemical knowledge. About this period he began to number among his acquaintances Selden, Oughtred, and Dr Wharton.

The wealth he acquired by his marriage engaged him in several disputes, and the lady herself at last made an attack upon him in chancery, but he was honourably acquitted, and the lady restored to her affectionate husband. His active industry never wearied, and he next attended to the study of antiquity and the investigation of records. Along with Sir W. Dugdale, he about this period traced a Roman road to Lichfield. Abandoning all other pursuits, he began to make preparations for his *History of the Order of the Garter*. Upon a visit to Oxford, he gave a full description of the coins bequeathed to that university by Laud; and about this time John Tradesant, the famous gardener of Lambeth, presented him with the collection of curiosities which both he and his father had procured.

Upon the restoration, Ashmole was greatly respected by the king, who made him Windsor herald, and employed him to give a description of the royal medals. The offices of commissioner and comptroller of excise were conferred upon him; and being called to the bar in the Middle Temple, he was afterwards admitted a fellow of the Royal Society. The university of Oxford conferred upon him the degree of doctor of physic; and several other employments and emoluments were given him, until he rose to the highest eminence in the literary world. About this time his second wife died, and he married the daughter of his friend Sir W. Dugdale. In May 1662 he addressed his great work to the king, entitled *The Institution, Laws, and Ceremonies of the most noble Order of the Garter*; folio, London, 1672. In favour of his brother-in-law Mr Dugdale, he resigned his office of herald of Windsor; and when offered the office of garter king-at-arms, he declined it in favour of Sir W. Dugdale. About this time a fire broke out in one of the chambers of the temple

adjacent to his, and consumed a library which he had been collecting during the course of 33 years, together with 9000 coins and many valuable antiquities; but his manuscripts and gold medals fortunately were saved. In 1683 he sent his manuscripts and curiosities to the university of Oxford, which laid the foundation of the *Museum Ashmoleanum*, still in Oxford. On the death of Sir W. Dugdale, he refused a second time the office which that gentleman had enjoyed. He died at the age of 76, and was interred in the church of Great Lambeth.

ASHRUFF, an ancient and formerly splendid city of Persia, adorned with a magnificent palace built by Shah Abbas, which was his favourite residence. It is situated on the shore of a bay, on the southern coast of the Caspian Sea. This palace is described in glowing terms by Hanway, who saw it in its splendour. It was visited by

Fraser in 1821, who found it a heap of ruins; and the town appeared to have suffered equally with the royal establishment. Ashruff was formerly said to have 300 baths within its walls; but it now contains only 500 houses, which are thinly scattered through an extensive jungle. It is about 70 miles west of Astrabad. Long. 53. 15. E. Lat. 36. 50. N.

ASHTON-UNDER-LINE, a large parish in the hundred of Salford and county of Lancaster, distant 5 miles from Manchester and 185 from London. It is one of those large places which within a few years has risen to wealth and populousness from the cotton manufactories. It is situated on the river Tame, and has the benefit of a navigable canal to Manchester, Rochdale, and Lancaster. The parish contains the hamlets of Hartshead, Hay, Moreley, and Staley Bridge. Population in 1801, 15,632; in 1811, 19,052; and in 1821, 25,967.

Asia.

A S I A.

THIS division of the globe is distinguished by its vast extent; by the striking character of its interior geography; above all by the stupendous revolutions of which it has been the scene; and, lastly, by the high antiquity of its civilization, of which we can still faintly trace the precious remains. Stretching from the southern hemisphere into the northern regions of perpetual winter, it comprises within its bounds the opposite extremes of heat and cold; all the varieties consequently of the animal and vegetable tribes; and that still more interesting variety which the irresistible law of climate impresses on the human species. The surface of Asia, towering to its height far above the regions of perpetual snow, presents, when superficially examined, a confused mass of lofty mountains, diverging into an endless variety of inferior ridges, apparently without plan or system. But a more attentive survey discloses, amid the bold irregularities of nature, the same order and unity of design in the structure of this great continent, as in all the other works of creation.

Asia was the earliest abode of the human race; and, when all the other parts of the world were either uninhabited or sunk in barbarism, it was the seat of great empires and of flourishing and splendid cities, of commerce, of literature, and of all the arts of civilized life. But its early prosperity was blighted by the ruthless devastations of war; its populous cities were utterly destroyed, so that the spot on which many of them stood is now only marked by masses of ruins; their arts and literature have perished; and in such fragments of their writing as still survive, all meaning is buried under the impenetrable veil of an ancient and unknown character. In touching on the various topics which are comprehended under the designation of Asia, it must be remembered that in the following article we are to confine our attention to such general views of its geography, history, institutions, policy, and manners, as will not supersede a more particular description of its various states under their respective designations.

The name of Asia was at first applied by Homer and others of the ancient poets and historians to a small district of Lydia, occupied by a tribe called Asiones, who inhabited a city of the name of Asia. The Greeks, gradually enlarging their discoveries in those eastern countries, still retained the original name, until it embraced the whole of Asia Minor and the countries to the east; and it was at last applied to all the vast regions which subsequent discoveries have brought to light.

The limits of Asia are in some cases marked out by nature, and admit of no dispute; in other parts they are

not very clearly defined, and have been differently settled by geographers, according to their own notions of propriety or distinctness. The modern innovation or improvement of erecting the Indian Archipelago and the numerous islands scattered over the Pacific Ocean into a fifth division of the globe, under the title of Australasia, has given rise to some difficulties in fixing the limits of the continent on the south-east. According to some, the Philippines, the Moluccas, the Celebes, Borneo, Java, and Sumatra, should still be included within the boundaries of Asia, leaving on the east the islands of Papua and New Holland to form the western limits of Australasia. Others, however, are for giving the whole Indian Archipelago to Australasia, on the ground that there can be no possible reason for detaching the Philippines and the other islands from the chain of which they evidently form a part, and assigning them to Asia; that they form one entire mass, which presents no natural point of separation; and that on this account the passage between the Philippine Islands and Formosa and the Straits of Malacca constitutes the most natural boundary of Asia on the east. According to this division, all the islands to the east and south of this line, as far as New Zealand and the Society Islands, would belong to Australasia, the continent of which, or the principal mass of land, would be formed by the immense island of New Holland. But this division, simple and distinct though it may appear, has not been generally adopted by geographers, who have assigned for the western boundary of Asia a line passing from Kerguelen's Land to the north-east, cutting off on the west the islands of Timorlaut, Ceram, Mysol, and Salwatty, and on the east the island of Papua or New Guinea, and stopping at the 132d degree of east longitude, at the equator; thus giving to Asia the fertile islands of Sumatra and Java, the great island of Bornéo, Amboyna and the Spice Islands, the Celebes Islands, and to the north of the equator the Philippines, the Pelew Isles, the Carolinas, the Ladrões, the isles of Japan, the Kurile Isles, and, beyond the latitude of 50 degrees, the Aleutian or Fox Islands. The other boundaries of Asia are, on the south the Indian Ocean, and on the south-west the Straits of Babelmandib and the Red Sea, separating it from Africa, with which its only point of junction is by the Isthmus of Suez. Asia is divided from Europe towards the west by the Mediterranean, the Archipelago, the Straits of the Dardanelles and of Constantinople, the Black Sea, the Straits of Caffa, and the Sea of Azof. Here this natural boundary ceases; and from the Straits of Caffa to those of Waigatz in the Northern Ocean different boundaries have

Asia.

been assumed. Some will have the ancient Tanais, now the Don, to be the natural boundary between the two continents of Europe and Asia. But besides that the Don has too winding a course for this purpose, it soon terminates, and we are then left to find our way to the Northern Ocean by an arbitrary line, which has accordingly been sometimes traced as the western limit of Asia from the mouth of the Don to that of the Dwina in the White Sea. But in all cases a natural is to be preferred to an artificial boundary; and the line which leaves the smallest space to be filled up by the fancy of geographers is surely the best. On this ground the Uralian Mountains, which stretch from the 50th degree of north latitude in a northern direction, to the sea of Kara in the Arctic Ocean, constitute a strongly marked boundary between Northern Asia and Europe; and in order to avail ourselves of this boundary, we must approach the Caspian from the Black Sea; and here, therefore, the line of separation between Asia and Europe will run eastward along the rivers Manitch and Kuma, the first flowing by a westerly course into the north-eastern angle of the sea of Azof, and the second eastward into the Caspian. From the mouth of the Kuma the Caspian Sea will mark the frontier of Asia to the mouth of the river Ural, which, along with the Ural Mountains, will complete the western boundary as far as the Straits of Waigatz. From these straits the Frozen Ocean, of which very little is known, bounds the northern shores of Asia to Behring's Straits, which separate the Asiatic from the American continent. From Behring's Straits the Pacific Ocean extends along the eastern shores of Asia to the Straits of Malacca.

Extent.

Asia contains a larger area than any of the other divisions of the globe. Europe is estimated to be 2000 miles in breadth, and nearly 3000 in length; Africa about 4300 miles by 4140; and America about 10,000 miles by the average breadth of 2000. The length of the Asiatic continent, taken obliquely from the Isthmus of Suez to Behring's Straits, is about 7370 miles; and its breadth from north to south, from Cape Comorin in India to Cape Taimura in Siberia, is about 4230 miles. Under the 30th parallel, from Suez to Nanking, its length is less than 6000 miles; from the Straits of the Dardanelles to Cova it is 6000 miles; and under the polar circle it is about 4230 miles. Asia is not of the same irregular form as America, nor is it, like that continent, broken into two natural divisions of North and South. It forms, like Europe and Africa, one continuous mass of solid continent. It is surrounded on all sides except the west by the sea; and, by the provident economy of nature, it has on this side, for half its length, the two great navigable inlets of the Red Sea, which for the space of 1400 miles divides Arabia from Egypt and Abyssinia; and of the Mediterranean, which, penetrating into the land from the west to the depth of nearly 2000 miles, and skirting the whole extent of the European and African shores, gives to Asia a sea-coast of nearly 1500 miles in extent, and secures a navigable communication on this side with the Atlantic Ocean, as well as with Africa and Europe. The northern shores of Asia are occasionally irregular and broken, and indented with some deep inlets, which it is useless to enumerate, as they can never, in those frozen regions, be subservient to the purposes of commerce. On the eastern shore there is the sea of Ochotsk, in breadth between 300 and 400 miles, inclosed on the east by the peninsula of Kamtschatka, projecting southward to a great length, and running out into the Kurile Islands; and on the west by the shores of Siberia, part of Chinese Tartary, and the island of Saghalien. The islands of Japan, which commence where the Kurile Islands terminate, stretch along the shore for above 600 miles, and inclose between them and the coast of Chinese Tar-

tary the Sea of Japan. These islands are succeeded as we advance southward by the Loochoo and other islands, by the large island of Formosa, and finally by the Philippines, Celebes, Borneo, Sumatra, Java, and other groups of the Indian Archipelago. Between the islands of Japan and the coast of Corea, which shoots out southward, is the Strait of Corea, 60 miles in breadth; and between the coast of Corea on the east and the Chinese shore on the other, is inclosed the Yellow Sea, which penetrates northward into the land, and forms a deep inlet, which is of great utility to the commerce and navigation of the northern provinces of China. The southern shore of Asia, from Cambodia to the Red Sea, presents an immense waving line, the ocean and the land alternately encroaching on each other, and forming immense bays and gulfs, and peninsulated tracts of land. Thus, on the eastern extremity, the Gulf of Siam is formed by the kingdom of Cambodia on the one side, and on the other by the peninsula of Malacca, the most southern point of Asia; and westward of this peninsula the Indian Ocean, advancing northward, forms the Bay of Bengal, bounded on the east and west by the two great Indian peninsulas. The same Indian Ocean makes another deep inroad into the land, between Arabia on the west and Hindostan on the east; and towards the north-western frontier of Hindostan it forms the two smaller gulfs of Cutch and of Cambay. On the opposite shore it penetrates deeply into the land, and forms the Persian Gulf, which divides the Persian from the Arabian shore, and is 600 miles in length and 220 miles in its greatest breadth, though at the entrance it is not above 55 miles broad.

The islands of Asia on its southern shore are the Andaman Islands, the Mergui Archipelago, and the Nicobar Isles on the eastern side of the Bay of Bengal; and on the opposite coast of Coromandel the large island of Ceylon. The Laccadive and Maldiva Islands lie off the coast of Malabar; and in the Persian Gulf is the celebrated island of Ormuz, formerly the seat of a splendid city and of an extensive commerce. In the Mediterranean are the islands of Cyprus and Rhodes, which belong to Asia.

The interior structure of this continent is on a scale of Physical peculiar magnificence: its mountains are of stupendous aspect, height; and these, together with its great rivers and its vast and boundless plains, impress on the mind the highest conceptions of natural grandeur. America, which vies in some respects with Asia in its imposing aspect, is nevertheless formed on an entirely different plan. It is long in proportion to its breadth; and throughout its whole length, from Cape Pilaes in the Straits of Magellan to its northern limits on the Frozen Ocean, runs the vast ridge of the Cordilleras in South America and the Rocky Mountains in North America, which, rising suddenly and abruptly to their height about 200 or 300 miles from the Pacific Ocean, but sloping more gradually towards the Atlantic for the space of 1500 or 2000 miles, give to the country its peculiar form and character. Asia, on the other hand, which is a more solid and compact territory, attains its highest elevation towards the centre of the country; and Central Asia is accordingly a vast platform, of an irregular figure, raised to a great height above the surrounding country, and faced on each side with an immense mountain-wall, formed of enormous rocks and peaks, which tower into the regions of perpetual snow.

The high land which these mountains seem to support on all sides reaches in a direction north and south about 1200 miles, namely, from the 30th to the 50th degree of north latitude; and in length about 2000 miles east and west, from the Caspian Sea to the Lake of Baikal on the north, and on the south from the sources of the Indus to those of the Burrampooter. It is the largest tract of elevated ground which is to be found in the globe, and has been

Asia.

generally distinguished by the appellation of Tartary, being the native country of all those savage tribes which, under the names of Huns, Tartars, Turks, or Mongols, have at different periods desolated the world. It contains generally the extensive country of Thibet, which lies on the northern side of the Himalaya range; Chinese Tartary in the east; and, to the west of the Chinese empire, Independent Tartary, which lies on the northern declivity of the great ridge, and comprehends the countries watered by the Jaxartes and the Oxus, as far west as the Lake Aral and the Caspian Sea; in which are Buckharia, Balk, the cities of Buckharia, Samarcand, Khyvah, &c. and which may be more distinctly pointed out as the country that lies between the frontiers of China on the east, of Persia on the south, and of Russia on the north. The high land of Central Asia constitutes the proper country of Tartary, and is generally of a rude and desolate aspect. It consists of low rocky hills, destitute of vegetation; of extensive arid plains; and occasionally, for the space of 1000 miles, of great deserts of loose sand, which being carried about by the winds, is raised aloft in drifting clouds, as in Arabia and Africa, and adds greatly to the danger of journeying in those inhospitable regions. The cold of winter is piercing and severe, from which the Russian embassy, in their journey to Peking through the deserts of Cobi in 1820, suffered grievously in the month of October, the thermometer being frequently below zero; while in summer the country is often afflicted with long-continued drought, which burns up the pasture, and occasions great mortality among the cattle, the chief subsistence of the pastoral tribes by whom this region is inhabited.¹ But the uniform dreariness of the scene is at times relieved by flowing rivers, and also by luxuriant meadows, on which the inhabitants feed their flocks, shifting their habitations with the seasons, and wandering over the desert in quest of pasture. The ridges of mountains which encompass and uphold the great central plain of Asia gradually subside, though somewhat irregularly, into lower ridges, with intervening and fertile valleys, and finally into the plains, which spread outward, as from a common centre, to the sea. Thus, on the north of the Altai Mountains we have the vast expanse of the Siberian plains, through which the great rivers, the Irtisch, the Yenesei, and the Lena, roll their lazy currents to the Northern Ocean. On the eastern declivity, which is deversified with some lofty ranges of mountains, stretches out the empire of China, with the extensive regions of Chinese Tartary; and the rivers Hoangho and Yang-tse-Kiang here pursue an easterly course to the Pacific, while the great river Amur is turned towards the north by a ridge of mountains that diverges from the great body of high land. On the south the mountainous ridge of the Himalaya descends into the low country of Hindostan and India beyond the Ganges; while the western crest of mountains, falling to a lower level, forms the table-land of Persia and the mountainous countries of Western Asia, until, in the south, it finally subsides into the Arabian mountains and plains.

The southern front of Central Asia overlooks Hindostan and the countries to the east, and consists of the great ridge of the Himalaya or Snowy Mountains, which, commencing near the Burrampooter on the east, run in a direction nearly north-west, as far as the country of Cashmere, forming the magnificent boundary of Bengal on the north. From Cashmere the general direction of the ridge is south-west, as far as the snowy peak of Hindoo Coosh, to the north of Cabul, in long. 69. 12. E. The name of Hindoo Coosh is applied to the whole of this ridge, which

declines in its progress westward to a lower level, and is neither so conspicuous among the mountain ridges by which it is surrounded, nor does it any longer present a continued line of perpetual snow. It is crossed by various routes from Candahar northward to Balk, about 50 miles west, where, in the mountain passes, snow is only found for four months in the year. Those mountains, in extending westward to Herat, in long. 62. 15. E., still continue to decline in height, and appear to be lost among the confused masses of the Paropamisan chain.

For a long period Europeans were but imperfectly acquainted with those interesting regions of interior Asia, and the Andes of America were supposed greatly to exceed in height this mountainous barrier of Hindostan. But since the gradual extension of the British conquests in Central India, several enterprising travellers have ascended these mountainous tracts; and it is now ascertained, from the accurate mensurations of Captain Webb and others, that their loftiest summits exceed the height of any other mountains in the world. The height of the Andes has indeed been underrated, as well as that of the Himalaya range. Chimborazo, estimated by Humboldt to rise 21,440 feet above the level of the sea, was formerly supposed to be the most elevated peak of those mountains. But from subsequent observations made by Mr Pentland, it appears that the summit of Illimani is 24,350 feet, that of Sorate 25,400 feet in height,² which is still somewhat inferior to the highest summits of the Asiatic chain, 27 different peaks of which were found from Mr Webb's corrected observations to range from an altitude of 17,994 to 25,669 feet in the Hindoo Coosh Mountains, which are a continuation of the Himalaya chain to the west. Lieutenant Macartney, who accompanied the British embassy of Mr Elphinstone into Cabul, found one of the highest peaks to rise 20,493 feet above the level of the sea. The elevated table-land of Central Asia was calculated by Captain Webb to stand generally at a level of 15,000 feet. The lofty summits of these stupendous mountains, towering aloft in all their natural majesty, fill the mind of every traveller with astonishment and awe; and the bright outline of white, when it is projected on the deep azure of a cloudless sky, is seen at the prodigious distance of 150, and, according to some, of 250 miles.

To the south of the main ridges of the Himalaya and Hindoo Coosh the land declines from its height, and presents a lower terrace of mountains, which runs parallel to the great range, and by which, as well as by branches issuing from it, the country is still rendered sufficiently rugged, though there are intervening valleys of great beauty and fertility. In the hilly districts thus formed under the higher mountains are the countries of Assam, Bootan, Nepaul, Kumaon, and Sirenagur. Those lower hills rise with a steep ascent from the plains of Bengal. According to Major Rennell, the southernmost ridge of the Bootan Mountains attains nearly a mile and a half of perpendicular height in a horizontal distance of 15 miles; and, from the summit, the traveller looks back with astonishment on the extensive prospect of the plains beneath him. Where the great range changes to a westerly direction, near the sources of the Indus and the Ganges, the lower mountains are separated from it by a wider interval, which is occupied by the high valley of Cashmere; and to the south and south-west is a mountainous country, which on the north bounds the Punjaub, or the country of the five rivers, namely, the head streams of the Indus, which were crossed by Alexander the Great in his invasion of India. To the south of those well-watered

² *Edinburgh Review*, No. c. p. 365.

Asia.

plains extends a tract of sandy desert almost to the Gulf of Cutch on the Indian Ocean. From the Hindoo Coosh Mountains several extensive ranges, though of inferior height, branch off to the south and west, and spread over the country to the west of the Indus as far as the Indian Ocean and the Persian Gulf. Some of these, such as the Soliman range, are still diversified with snowy peaks, though their height gradually declines as they recede from the central high lands of the country.

At the distance of about 200 miles to the north of the great Himalaya ridge there is another inner range of lofty mountains, which, though it does not rise quite so high as the exterior ridge, runs parallel to it, and is known under the appellation of Mus-tag or Moos Taugh, signifying, in the dialect of the country, Ice-hill. It extends as far as the 67th degree of east longitude; and between it and the main ridge of Himalaya and Hindoo Coosh is inclosed an elevated table-land, extending eastward into Thibet, though it is but little known beyond the meridian of Ladac, in 75. 12. E. The vast deserts of Central Asia are indeed rendered almost inaccessible by the mountain-wall which surrounds them; and hence a comparatively small portion of the country has been explored by European travellers.

The western crest of the great Asiatic high lands is formed by a range of mountains which leaves the chain of Hindoo Coosh in 71° east longitude, in a direction east of north, and is known by the name of Belur Tag, a corruption, according to Elphinstone, of Beloot Taugh, or Cloudy Mountains. This range of mountains, though inferior in height to that of Hindoo Coosh, has generally snow on its summits. It crosses the ridge of Moos Taugh, and is continued towards the north till it reaches the chief range of the Altai Mountains, which form the northern barrier of the great central plains. It is the natural boundary between Chinese and Independent Tartary, and the dividing ridge from which the rivers flow east and west into both countries. Here is also the dividing ridge between the Oxus and the Jaxartes, which flow northward into the lake of Aral, and the great Indus, which takes a southern course to the Indian ocean.

From this great western boundary of the central plains the country descends slowly to a lower level by successive ridges of rugged and desolate mountains, intermingled with high and desert plains, and fertile spots scattered at great distances over the barren waste. Towards the north these mountainous ridges do not seem to extend beyond the sea of Aral, or about half way between the high land of the interior and the Caspian Sea, leaving on the north-west of the Aral vast plains, the habitation of pastoral tribes; and on the west of the Caspian Sea the desert expanse of Khauresme or Carisme, the abode of predatory hordes, who infest the surrounding countries. To the south of the Caspian extends the great table-land of Persia, which consists of mountainous ridges, varied with elevated and barren plains, which, judging from the extraordinary severity of the winter cold, must be raised from 3000 to 4000 feet above the level of the sea. Persia is situated in this manner on the great western declivity of Asia; and its mountains are connected with those of the great central ridge of Hindoo Coosh, which, extending westward, under the name of the Paropamisian Mountains, to the south of Balk and to the north of Cabul or Afghanistan, sends forth branches which spread over Persia in various directions in the south as well as in the north. The northern ridge, taking a north-westerly course, turns westward to the Caspian Sea, diverging in its progress into various ramifications towards the south. It passes along the southern shore of the Caspian; and for a space of 1500 miles, namely, from the eastern

Asia.

country of Balk to the Persian province of Azerbaijan, west of the Caspian, it appears to form the boundary and rampart wall of a great table-land to the south, which extends eastward beyond the Persian territory, and is estimated to be 3000 or 4000 feet higher than the flat country between it and the Caspian Sea on the north, or than the desert which extends eastward of this sea into the country of Balk; and so steep are those mountains, generally known by the name of the Elburz Mountains, on the north, that the low country comes suddenly up to their base as to a wall. This northern chain of mountains appears to unite, in the western provinces of Persia, with another chain issuing from the great western coast of the central plains farther to the south, and to form that mass of mountains which separate Armenia from Mesopotamia, and from which diverge westward into Asia Minor, along the shores of the Mediterranean, the celebrated ridge known to the ancients under the name of Mount Taurus, and northward between the Black Sea and the Caspian the mountain chain of Caucasus, which rises to a great height, being in many parts above the line of perpetual snow. This appears to be the highest continued tract of elevated territory in Western Asia; and it gives rise to the great streams of the Euphrates and the Tigris, which flow southward into the Persian Gulf, as well as those rivers flowing northward into the Euxine; also to the Aras, the ancient Araxes; the Kur and the Kuma, which run east into the Caspian; and to the Kuban, and other inferior streams, which, by a westerly course, reach the Black Sea. This mountainous tract of country has chiefly a southern exposure, and the dividing ridge between the waters which flow south and north being on the borders of the Black Sea, the streams flowing northward from the mountain tract into this sea are consequently insignificant in size compared with the Tigris and the Euphrates, which run down its southern declivity. Towards the east the streams, having to run over a larger space before they reach the Caspian Sea, are of course more considerable.

From this elevated tract of country, which takes a westerly course on leaving the great ridge of the Hindoo Coosh Mountains, its altitude declining as it advances in this direction, various lateral ridges, of inferior height to the main ridge, project towards the south, inclosing between them extensive valleys or low countries. The most westerly of these cross ridges is that which begins from the body of Taurus, near the sources of the Euphrates, at the northern extremity of Syria. This ridge proceeds towards the south, and afterwards inclining to the south-west, it skirts the western shore of the Mediterranean, where it is known under the names of Amman, Sinai, Syria, &c.; and in its course southward it forms the two ridges of Libanus or Lebanon, the mountain of this name being of great height, as is indicated by its snow-clad top, and the inferior ridge of Anti-Libanus to the east. Having passed the Mediterranean and the southern border of Palestine, it advances to the eastern coast of the Red Sea, where it spreads out and forms the central mass of the Arabian mountains, and the ridges which run along the eastern shores of the Red Sea and terminate in Arabia Felix, on the shores of the Indian Ocean.

The northern front of the great central plain of Asia is formed by the vast range of the Altai Mountains, which, under different names, traverse the whole extent of this continent from east to west for a space of not less than 5000 miles. At their western extremity they join the Ural Mountains, which seem to be a continuation of them; and they stretch almost due north in a direction nearly parallel to the course of the Oby, until they reach the shores of the Frozen Ocean, and, crossing the narrow

strait of Waigatz, they terminate amid the rigours of winter in the desolate island of Nova Zembla. On the east the Altai Mountains send forth two ridges, which appear, in the same manner as the Ural ridge, to be a continuation of the original chain, and which reach to the utmost extremities of Asia. One of these, under the name of the Zangai or Changai Mountains, extends in a direction south-east, and, attaining a great height, terminates in the Gulf of Corea, to the northward of Peking. Another chain, namely, the Daouria or Nertschinsk Mountains, proceeds north-eastward along the Gulf or Sea of Ochotsk, and only terminates with the limits of the continent in the vicinity of Behring's Straits. From this chain an inferior one breaks off, and taking a south-easterly direction, penetrates to the southern extremity of the peninsula of Kamtschatka. This northern bulwark of the central high land of Asia is greatly inferior in height to the Himalaya and Hindoo Coosh Mountains, the boundary on the south. Its elevation is not supposed to exceed 5000 or 6000 feet, which is sufficient, however, in that northern latitude, to bring it within the line of perpetual snow. Besides the outward ridge, which faces the north, there are interior and parallel ridges, imperfectly known, and between which the country spreads out into elevated plains. It is in these interior and apparently higher mountains that the head waters are to be found of the Irtisch, the Oby, the Yenesei, and the Lena, which pierce through deep defiles in the outer ridge of the Altai Mountains, and make their way through the plains of Siberia to the Frozen Ocean. The great river Amour, however, being confined by this barrier, and turned aside to the west into Chinese Tartary, finally reaches, by a northerly course, the Sea of Ochotsk. To the north of the Altai Mountains the country subsides into the low country of Siberia, which, with occasional ranges of high ground, presents one vast plain from the base of the Altai Mountains to the Arctic Sea. Here are three tracts, or steppes as they are called, which extend for hundreds of miles on a dead level, and exhibit the same aspect. Of these the steppe of the Issim extends, in the south-western part of Asiatic Russia, along the base of the Altai chain, from the Ural river and the Caspian Sea, across the sources of the Tobol, the Itchim, and the Irtisch. The steppe of the Irtisch reaches from that river to the Yenesei, a space of 1000 miles from east to west; and it seems to be continued between the lower course of the streams as far as the Frozen Ocean. A similar tract reaches from the Yenesei to the Lena. These plains are generally barren: some of them abound in rock-salt and in salt lakes, others are covered with deep forests, and some parts are fitted for agriculture or pasturage. They are of the most dreary aspect; and as they advance into the northern latitudes, they combine the double evil of a barren soil and a severe climate.

Of the mountains inclosing the great plain of Central Asia on the east, and which subside into the lower country of China, we cannot attempt any geographical description, as they are very imperfectly known. From the nature of the country, however, which is known, and from the direction of its mountains and streams, we may deduce some general inferences as to those regions which are unknown. The great chain of the Himalaya Mountains, on entering the peninsula beyond the Ganges, inclines towards the south; and numerous chains of inferior magnitude breaking off in this direction, divide that peninsula into long parallel valleys, in which the great streams of

the Irrawaddy, the Menam, the Maygue, and the Japanese, flow southward to the Indian Ocean. Those mountains which thus break off from the Himalaya range to the south also diverge, without doubt, towards the north; and they will thus form the western frontier of China, and the mountain wall which supports the central table-land on the east. We are ignorant of the height or other particulars regarding this chain. But from the direction of the two great rivers, the Hoangho or Yellow River, and the Yang-tse-Kiang or Blue River, which water the central regions of China, and which have their sources in the interior deserts, it is evident that from the central high lands the country must be a continued declivity, varied occasionally with lower terraces of hills, to the Eastern Ocean. A range of mountains runs through the southern provinces of China, which seems to be a prolongation, on a lower scale, of the great Himalaya ridge; and a lofty chain of naked rocks, already noticed, runs along the southern frontier, and separates China from Tartary. It is a branch of those mountains which turn aside the river Hoangho into a northerly direction; and it is only by a circuitous and winding turn that it regains its original course towards the east.

The rivers of Asia correspond in grandeur with all the Rivers. other great natural features of the country. A river, it is evident, will be great or small according to the extent of the basin or valley of which it is the natural drain, and according also as it recedes from or approaches the regions of rain which lie under the equator. The largest rivers are accordingly those which have the longest course, and that course within the tropics or near to the equator; and all the great rivers of the globe will be found to coincide with this hypothesis; many of those in high latitudes with a long course being inferior in magnitude to the rivers within the tropics which have a shorter course, and which are fed by the periodical rains. The Amazons is unquestionably the largest river in the world. It pours into the ocean a stream of the greatest magnitude, being 180 miles broad at its mouth, and of an amazing depth; and it combines the two necessary conditions of a great river. It has a long course of fully 3000 miles (chiefly within the 6th or 7th degree of S. lat., where it crosses nearly the whole breadth of America), swollen into a most prodigious volume of water by the almost constant rains of the equator. The Mississippi in North America has a long course, including its windings, of nearly 3000 miles; and it is the only drain of that vast valley situated between the Rocky Mountains on the west and the Allegany Mountains on the east, the area of which cannot be less than 2,000,000 of square miles. But its course lies without the limits of the tropical rains; and it wants, consequently, one of the requisites of a great river. It will be found, accordingly, that it does not pour into the ocean such a volume of water as the Orinoco, the course of which is not estimated to exceed 1300 or 1400 miles; and its basin is inferior in extent by two thirds to that of the Mississippi. Yet this latter, though a magnificent stream, is not, opposite New Orleans, 102 miles from its mouth, above 132 feet deep during the inundation, and 4500 feet broad; while the Orinoco was found in the dry season at St Thomas, 250 miles from its mouth, to be 390 feet deep and 2300 feet broad.¹ In Africa, again, the Nile has a course of above 2000 miles, and it has its rise within the tropics. But its northerly course carries it away from the periodical rains into Northern Africa, where rain seldom or never

¹ Depons, *Voyage à la Partie Orientale de la Terre Ferme dans l'Amerique Meridionale*, 1801-2-3-4. The rise of the river during the rainy season is stated by the same author to be 13 fathoms opposite St Thomas. Tome iii. p. 301.

Asia.

falls; and hence, for the space of 1000 miles, it receives not the aid of a single tributary stream. It is merely the collected rains of the northern tropic, diminished rather than increased as they flow through the African deserts to the Mediterranean. Hence the magnitude of the Nile is not in proportion to the space over which it flows. It has not so large a stream as either the Orinoco or the Ganges, which, though they have each a shorter course, are yet swollen to a greater size by the tropical rains. If the Nile had flowed in an opposite direction towards the equator, it would have ranked in the first class of rivers. The vast expanse of Asia presents an ample area for the formation of the largest streams. In the interval which extends from the loftiest ridges of the central mountains, the multitudinous waters of the most distant regions may be poured into one common channel; and the rivers of Asia, therefore, from the space over which they flow, ought to be the greatest in the world. This, however, is not the case. They are indeed most magnificent streams, and present, in the roar and foam of their impatient waters while they are yet imprisoned within the mountains, in the violence with which their conflicting tides successively intermingle in their progress to the sea, and in the breadth and majesty of the overflowing stream sweeping over the plains, all the most imposing phenomena of the greatest rivers. But they are inferior in magnitude to the chief rivers of South America—to the Orinoco, and still more to the Amazons; and the explanation of this fact must be sought for in the position of Asia, of which only the southern extremity is within the region of the tropical rains. The solid mass of the Asiatic continent just reaches the northern tropic; and it is only the peninsular tracks of Arabia, Hindostan, and the narrow strip of Malacca, that shoot out beyond this boundary towards the equator. The greatest rivers of Asia, namely, the Ganges and the Indus, are consequently without the limits of the tropics. But in Asia the rainy season has a wider range than in Africa, where it does not extend beyond the northern tropic. In the tropical countries of Asia this season sets in with the south-west monsoon, which drives the gathering clouds from the Indian Ocean over the plains of Hindostan, and as far as the northern barrier of the Himalaya Mountains, by which their progress is at length arrested, and extends the periodical rains over the whole intervening country. Hence both the Ganges and the Indus are fed by these rains, though the northern latitude in which they flow would in Africa place them in the driest regions of the earth. They accordingly rank among the rivers of the first class, whether we look to their length of course or to the body of water which they pour into the ocean. They both have their rise in the great Himalaya ridge, among the regions of perpetual snow, at no great distance from each other, when they diverge—the Indus into a south-westerly, and the Ganges into a north-easterly course, according to the slope of the land, and reach the Indian Ocean exactly on opposite points of the peninsula of Hindostan. They form each the great drain of their respective valleys, and they have many tributaries, which it is unnecessary here to state in detail. The great river of the Brahmaputra, which is fully equal to the Ganges, has its source from the opposite side of the same mountains; and after a long easterly course among desert mountains, in which it approaches the confines of China, it winds towards the west by a vast circuit round the mountains, and joins the Ganges after a course of about 1600 miles. The other great rivers of Eastern Asia which flow down the southern declivity of the central mountains are, the Irrawaddy, which has its rise in the eastern mountains of Thibet, and, after a course of 1200 miles, falls by many mouths into the Gulf of Bengal; the Me-

nam, which falls into the Gulf of Siam; and the Camboja, which, rising in the northern mountains, after a course of nearly 2000 miles falls into the Chinese Sea to the east of the Gulf of Siam, in about lat. 10. S. The course of all these rivers lies more within the region of the rains than that of either the Indus or the Ganges; and the Irrawaddy, and especially the Camboja, are of great length. But the basins or valleys of which they are the outlets are long and narrow, and their collected waters are not sufficient for the formation of such large rivers as the Indus or the Ganges. Yet the Irrawaddy is of great magnitude; it has its delta and its periodical overflow; and during the rainy season it is a mile broad, and of great depth. It decreases during the dry season to half a mile in breadth and to a depth of eight feet. The Menam is not a river of any imposing magnitude; and of the Camboja we have but very imperfect accounts; but judging from the great length of its course, which is also within the region of the heaviest rains, its stream can hardly be inferior to the largest rivers of Asia. It is said to be navigable for large vessels 40 leagues from its mouth, to be in general two miles wide, and so deep that ships can approach almost close to its banks. The peninsula of Hindostan, which projects southward, and is subject to periodical deluges of rain, is not of sufficient space for the formation of any great river. Amid the lower ranges of mountains, the Nerbuddah, which in some countries would be thought a large river, takes its rise, and flows from east to west down the western slope of the great plain of Central India into the Gulf of Cambay; and here commences the mountain range of the Ghauts, which runs along the coast of Malabar to Cape Comorin, at the distance of not more than 100 miles; while from the opposite coast the intervening country extends from 300 to 700 miles; thus exhibiting on a small scale the formation of the American continent, which rises to its height at the distance of about 300 miles from the Pacific Ocean, leaving the vast space on the other side of the mountains to the Atlantic for the course of all the great rivers. In like manner, all the great rivers of Hindostan flow down the eastern declivity of the Ghaut Mountains, namely, the Mahanuddy, the Godavery, the Kistnah, the Tuptee, and the Cavery, which flow from the Ghauts in an easterly direction across the country to the Indian Ocean. The streams on the opposite declivity of the mountains have necessarily a short course, and are chiefly inconsiderable mountain torrents, except when they are swollen by the rains. The Euphrates and the Tigris, which have their origin in the mountains of Armenia, are the only other considerable rivers of Asia which flow southward into the ocean. They are not rivers of the first class, not nearly equalling either the Ganges or the Indus, though the Euphrates must be nearly equal to the Danube, the greatest river in Europe; and they are in no respect tropical rivers, as they derive their supplies from the melting of the snows, and from the spring and the winter rains. It is accordingly in January that the great overflow of the Euphrates takes place. It may be here remarked, that throughout Asia the countries without the limits of the monsoon depend on the rains, which generally fall in the spring, and more copiously in the winter, though these rains are far from being so regular as the rainy season within the tropics.

The great ridges of the Himalaya and Hindoo Coosh Mountains divide the rivers of Asia which flow southward to the Indian Ocean, from those which flow northward or eastward into the central deserts of Tartary. They do not appear, however, to be considerable; and are probably lost amid the wastes of sand extending over a great portion of that country, or in some of its interior lakes. On the north

Asia.

the Oxus, a great river, and the Jaxartes, of which the sources approach those of the Indus and the Ganges, being on the opposite sides of the same high land, emerge from the mountain deserts into the plains, and, after a long course, both reach the interior lake of Aral, to the east of the Caspian Sea. The great rivers in the east of Asia, namely, the Yang-tse-Kiang and the Hoangho, which rise in the unknown deserts of Thibet, and flow through China into the Eastern Seas, have each a course of extraordinary length; and they must no doubt pour a large stream into the ocean. But we have no accurate accounts of their size, neither of their breadth nor depth; and as they are not within the limits of the rains, the magnitude of their stream cannot be in proportion to its great length, as the rains of these northern regions never accumulate into such a body of water as the rains of the tropics. The great river Amour, which runs down the eastern declivity of the Asiatic high lands, is remarkable for the length of its course; but though it must be a great river, we have no accurate information respecting it.

On the north, where the central table-land of Asia declines towards the Frozen Ocean, there is ample space for the formation of rivers; and accordingly, through the vast and desolate wastes of Siberia flow the Irtisch, the Obi, the Yenesei, and the Lena, by a winding course, to the Arctic Sea. The whole breadth of Asia, from the Eastern Ocean to the Ural Mountains, is drained of its waters by these four rivers and their tributaries; and the Irtisch, the Yenesei, and the Lena, from their source in the unknown deserts of Chinese Tartary, must flow over a space of nearly 4000 miles, which greatly exceeds the course of the great Amazons. We know little as to the volume of water contained in these rivers, which, though it must be great, yet, judging from the magnitude of other rivers in the same latitude, cannot equal that of the great tropical rivers. The Volga is a large river; it has a great length of course; but its depth does not exceed 15 feet.¹ The basins of the northern rivers of Siberia are no doubt of great extent; but even though we estimate their streams at double the magnitude of the Volga, they will only attain a depth of 30 feet, which is not one tenth part the depth of the Orinoco, though, according to Major Rennel, it is equal to that of the Ganges.

Asia is distinguished by the variety and extent of its interior lakes; and its extensive table-lands, intersected by mountains, favour the collection of those masses of water. In general these lakes are distinguished by the saline, brackish, or sulphureous nature of their waters. Asia Minor contains numerous salt lakes which have no outlet, and some of them of considerable extent. To the west of the Caspian Sea are the lakes of Van and Urmia, Ooroomea or Shahee, the waters of which are intensely salt.² In Syria, the great chains of Libanus and Anti-Libanus contain several lakes, the most celebrated of which is the Lake Asphaltites or the Dead Sea in Palestine, whose bituminous waters cover a space of nearly 500 square miles. The Caspian Sea on the western declivity of the central heights is beyond all comparison the largest lake that is known, being in length 646 miles from north to south, and 265 in extreme breadth; while the greatest length of Lake Superior in North America is not more than 381 miles in length and 161 in breadth. Lake Aral, to the west of the Caspian Sea, is 150 miles in length by 60 in breadth; and to the east the lakes of Aksakol, Telegul, Balkashi or Palcati, and numerous smaller lakes, are scattered over the region which lies between the central mountains and the Caspian Sea. In

all these lakes the waters are salt or brackish. Persia contains in its salt deserts numerous small lakes; and also the large lake of Zere or Zurrah, which covers a space of 1000 square miles.

On the northern declivity of the table-land of Tartary are scattered numerous lakes, many of which are scarcely known by name in Europe, though they are of great extent, and are fed by the rivers from the surrounding mountains. Of these the Lake Tchany or Czany is the largest. The high plains in the table-land of Tartary and Thibet, environed on all sides by lofty mountains, are the receptacles of the imprisoned waters of these elevated regions. Near the southern ridge of this mountain tract is found the large and variously designated lake which gives rise to the Irtisch; and the southern plains, inclosed by the mountains of Chinese Tartary and Thibet, the most elevated summits of Asia, are said to contain considerable rivers, which are either lost in the sands or in interior lakes. The country of Thibet abounds in lakes, in most of which the waters are salt. Some of these are of great extent. The Terkiri, according to the accounts of the Chinese missionaries, from whom we derive our chief knowledge of these vast countries, is 60 miles long by 40 broad. The Kokonor, which signifies a great sea, is on the borders of China: it contains 1840 square miles, and a space of 600 miles on both sides of Lake Terkiri, and includes no less than 23 lakes, some of them of considerable extent. There are comparatively few lakes in the exterior plains of Asia.³ The Lake Baikal, in Upper Siberia, is 366 miles in length by from 20 to 53 in breadth. But Lower Siberia is one continued series of marshes, with intervening plains adapted for pasture. China contains few lakes, the country being one continued declivity; and from the same cause the peninsula of Hindostan contains not a single lake of any extent.

From its internal structure Asia does not possess the same advantages of navigable intercourse as the other divisions of the globe. From the peculiar structure of the American continent, all the great rivers flow to the east or to the south-east, some of them across almost the whole breadth of the continent, and scarcely leave any part far out of the reach of a navigable communication. North as well as South America has also a southern or eastern exposure, in consequence of which the Mississippi, the Orinoco, the Amazons, and the Plata rivers, flow either to the south or to the east, into the seats of civilization and of commerce. The structure of Asia is different: it is of the most imposing grandeur and simplicity, and is eminently calculated to impress on the mind an idea of vastness and of majesty; but it is not so well adapted for the purposes of internal improvement. From its form, which rises into a great table-land towards the centre, the rivers naturally descend on all sides to the sea, as radii from a common centre, leaving vast tracts and high plains a prey to perpetual drought and sterility, and without any navigable communication with the sea. Not that the great table-land of Asia, if we except the vast sandy deserts of Cobi and Shamo, presents such a uniform aspect of frightful wastes as is generally supposed. It is not by any means wholly destitute of water and vegetation, but contains extensive plains fertilized by rivers flowing into interior lakes, and well adapted for pasturage, the chief occupation of the inhabitants, and which, if they were properly cultivated, would yield grain and other produce. But the want of moisture is still the chief disadvantage; and the streams which arise in this elevated region having no outlet to the sea, afford no facilities of

³ Histoire Général des Voyages, tome vii. p. 108.

Asia.

exterior intercourse. This disadvantage necessarily belongs to a country of elevated plains of immense extent, fenced round with mountains, and thus insulated from and almost unknown to the whole world besides. A lake which does not communicate with the sea merely facilitates the communications between its own shores. Hence it is of no material use in the intercourse of a country; and the nature of the ground to which these lakes owe their formation is a positive disadvantage, as its effect is to intercept the interior waters in their progress to the sea, and to collect them into a large reservoir in the heart of the country. Thus the Oxus and the Jaxartes flow into the Aral; and the Caspian Sea, which presents no facilities for internal improvement, is the recipient of some very great rivers. But if they had reached the Black Sea, how much more would they have conduced to the improvement of the country. The great rivers of what we may call Southern Asia, namely, the Euphrates, the Tigris, the Indus, the Ganges, and the streams which run into the Indian Ocean in the peninsula beyond the Ganges, are well adapted for navigation and commerce; and the Ganges more especially is of vast advantage both in fertilizing the soil and improving the intercourse of the country through which it flows. The course of the other great rivers, such as the Indus, &c. would equally promote the same great objects; but the adjacent countries are inhabited by barbarous tribes, who neglect all those natural advantages. The Chinese rivers which wind across that country from the western mountains are rendered eminently subservient to navigation and commerce by that industrious people. But the course of the great rivers flowing from the central mountains into the Frozen Ocean, into which course they are turned by the northern exposure of Asia, is eminently unfavourable for the improvement of the country, as they are carried entirely out of the seats of commerce and wealth to the Arctic Sea, the gloomy abode of perpetual winter. These great rivers, therefore, the Irtysh, the Obi, the Yenesei, and the Lena, owing to their having a northern course, must for ever remain useless to commerce and navigation. They lead to countries from which no benefit can ever be derived, to seas bound up in perpetual ice, and to regions of sterility and cold, which mankind desire to fly from rather than to visit. These rivers, great and navigable though they be, present no outlet to the produce of the interior; nor can they greatly aid the general routes of the traveller in crossing Siberia. They afford considerable advantages, however, especially in their upper streams, for carrying goods into and from China. It is singular that to the west of the Ural Mountains the country should have a southern exposure, and the great rivers of northern Europe, accordingly, the Volga, the Don, and the Dnieper, flow with a southerly course into the Caspian or the Black Sea.

Great natural divisions.

From the general view which has been given of the form and interior structure of this great continent, and of the system of its mountains and rivers, it may be distinguished with advantage into five great natural divisions, namely, Central Asia, Southern and Northern Asia, and Eastern and Western Asia.

1. Central Asia, or the great high lands, with their elevated plains and almost boundless wastes, is, in the eastern parts, chiefly within the limits of the Chinese dominions. It contains Thibet and Chinese Tartary, to whose powers we cannot assign any definite limits. But it is certain that in the south the dominion of China extends very far west, to the 80th degree at least, as it now borders with the British frontier in Hindostan, where Chinese horsemen are placed to guard, with their usual jealous policy, the celestial empire from intrusion. On the north the

territories of China border with those of Russia, and the whole intervening tract must be included under the Chinese dominion. But we know little of these wild and desolate regions; and it is uncertain how far the pastoral or predatory hordes which range over them are controlled by the Chinese authorities. The country of Thibet is also bounded by China on the east and on the north, though we cannot exactly determine the limits of their respective territories. Farther to the north the sway of China extends to the 78th degree of E. long., and includes the rich and populous Mahometan towns of Kashgar, in long. 76. 5. 45. E. lat. 39. 25. N., and Yarkund, in long. 78. 27. 45. E. lat. 38. 19. N.; the first reckoned to contain 80,000 inhabitants. It does not seem to be separated from Independent Tartary by any distinct boundary. The countries near the sources of the Indus and the Oxus, about the 78th degree of E. long., are inhabited by wild and independent tribes, who, like most of their race, subsist by pasturage or plunder. Here is Balk, the ancient Bactria or Bactriana, where there are several chiefs who rule over their rude and intractable subjects with a precarious sway. Here is also the city of Buckharia, which, with the surrounding country, is ruled by an independent sovereign; and the independent states of Khyvah and Kokaun, the first extending on and near the banks of the Oxus, between 100 and 200 miles, and the latter divided into two parts by the Jaxartes, and reckoned to be more than 200 miles in length and 150 in breadth. To the west, as far as the Caspian Sea, is the proper region of Independent Tartary, bounded on all sides by the Russian, Chinese, and Persian empires.

2. Southern Asia includes Hindostan from the Himalaya Mountains; on the west Afghanistan and the independent tribes scattered in the lower valley of the Indus; the kingdom of Nepal on the east; the hilly country of Bootan, the Burman empire, the peninsula of Malacca, and the kingdom of Camboja.

3. Western Asia contains Persia, the peninsula of Arabia, the extensive countries over which Turkey maintains a loose and uncertain authority, comprehending Mesopotamia, Armenia, Syria, and Palestine; Asia Minor, surrounded on the north, south, and west, by the Mediterranean and the Black Seas, and the mountain regions of Caucasus between the Black and the Caspian Seas.

4. Eastern Asia is occupied by the Chinese empire and by Chinese Tartary.

5. Northern Asia forms the Asiatic part of the Russian empire, which extends from the Altai Mountains to the Frozen Ocean.

Asia, extending from the equator to the Arctic Sea, necessarily possesses great variety of climate. But though here, as in every other country, the climate is regulated by the distance from the equator, this general law is modified by accidental causes, which it is curious to trace. In the wide extent of Asia great peculiarities of temperature occur, which cannot be very clearly explained. The system of the universe is conducted on so vast a scale that our faculties of observation do not keep pace with its great movements. How can we, for example, trace the rapid course of the winds, on which the temperature of countries so essentially depends, traversing as they do the whole space of the habitable globe at the rate of 1000 miles in 24 hours? How can we ascertain their origin and follow their progress, which is modified by the various interruptions of mountains, continents, and seas? How can we distinctly point out, amid such a complication of unknown facts, the connection between cause and effect? To such inquiries some uncertainty will always attach, and anomalies may appear of which we can offer no solution. In these circumstances, facts are our only

Asia.

sure guides; and to these, therefore, in the following observations, we shall endeavour to adhere.

The height of the land above the level of the sea is as sure a cause of cold as distance from the equator; and countries are not only cold in proportion to their height, but a mass of cold air is accumulated above them, which, being dispersed, is carried towards the equator, and extends the dominion of cold into the regions of heat. Land and water, also, are the causes either of heat or cold, according to their situation. The great mass of the ocean is little affected by the changes of the seasons; and it consequently preserves the medium temperature of the whole year. Hence the vicinity of the ocean cools the temperature of the equinoctial regions; and in higher latitudes it moderates the extremes both of heat and cold, being in winter of a higher temperature, and in summer of a lower temperature, than the superincumbent air. The surface of the earth, again, imbibes heat or cold much more readily than the ocean; and it is only at considerable depths that it is found to give the medium temperature of the year. The vicinity of land, therefore, in the polar countries, is the cause of cold, while in the southern regions of the equator it is an equally powerful cause of heat. Thus Africa, which extends so far to the south, and which contains a greater proportion of land within the tropics than any other division of the globe, is a vast store-house of heat, from which it is dispersed far and wide, and even reaches the shores of Europe in hot and parching winds; while, on the other hand, the breadth and extent of the American continent towards the north sufficiently accounts for the coldness of its climate, the north-west winds which sweep across its frozen wastes extending their inroads into the regions of heat as far sometimes as Mexico or Vera Cruz.¹ The influence of the ocean in moderating the severity of the winter is exemplified in the climate of Great Britain, where no such intense cold ever prevails as in corresponding latitudes on the continent of Europe, and more especially on that of Asia. The climate of a country is also affected by the direction of the winds; and hence the eastern shores of America, owing to the trade-winds, which blow from the east, and are cooled in their passage across the Atlantic, have not the same sultry heats as the opposite shores of Africa, where the same winds are heated to an intense degree in their passage over the burning deserts of the interior. The northern frontiers of Asia, and its prodigious elevation towards the centre, necessarily consign the greatest portion of it to the dominion of cold. Among the central mountains perpetual winter reigns; and from these snowy deserts the influence of cold is widely extended over the high plains of the interior. In Thibet, which is about the same latitude as Northern Africa or Arabia, namely, between the 30th and 35th degrees, there is a continuous and severe winter of three months, which is of such uniform severity that at its commencement the inhabitants kill their meat, and it is kept perfectly fresh for three months.² To the west, along the whole range of elevated land that extends into Persia and to the Caspian Sea, the climate is modified by the elevation of the ground. In the countries of Balk and Buckharia, which lie on the northern declivity of the great ridge of the Hindoo Coosh Mountains, in the same

latitude as the south of Europe, namely, the 39th and 40th degrees, and all along the banks of the Oxus, the climate is remarkably severe. For three months the winter is intensely cold, the wind being dry and piercing, and the snow lying deep on the ground. The rivers are all frozen over, and the Oxus during all that period is passable for caravans.³ The summer, again, is equally hot. Persia, in like manner, being nearly in the same latitude as Arabia, the hottest part of the earth, and having an excessively hot summer, has in the northern and central parts the severe winter of a northern climate, with drifting snow, which lies deep on the ground for three months; and this is owing entirely to its elevation, which is estimated by Fraser to be 4000 feet above the Caspian Sea.⁴ The lower valleys and exterior plains of Asia, which lie to the south of the Himalaya Mountains, including Arabia, the southern and flat parts of Persia, Hindostan, and India beyond the Ganges, constitute the tropical and warm regions of this continent, of which the climate, though it agrees in general with their position on the globe, still varies from local causes. Hindostan, for example, and India beyond the Ganges, though they approach nearer to the equator, are not nearly so hot as Arabia or the adjacent countries. The course of the seasons is also more constant; and it is here that we meet with those remarkable winds, the monsoons, which blow six months in opposite directions, from the south-west and north-east, with some slight variations, and which extend their influence over all the countries which lie between the mouth of the Indus and the Chinese Sea. The monsoons follow the course of the sun, and this fact points to the cause of the phenomenon. Heat and cold being the great agents which, by rarefying or condensing the air, disturb its equilibrium, and set the winds in motion, land, when it is heated by the solar rays, acts on the superincumbent air, and causes it to ascend, when it is immediately replaced by an irruption of cold air from the sea. Hence the regular sea-breeze which prevails in all the tropical islands during the day, and the opposite current from the land during the night; and this alternation of the sea and the land breezes, occasioned within 24 hours by the varying temperature of an island, is just an example of the effect that must be produced by a heated continent and by the change of the seasons. As the sun advances into the northern tropic, the land of Asia, Europe, and almost the whole of Africa, is heated by his influence; by which the air being rarefied, and rising aloft, a current of colder air rushes in from the sea. Accordingly it is found, that with the approach of summer, the plains of Hindostan, Burmah, and China, heated by the intense rays of a vertical sun, violently attract the cold air, which flows with a steady stream from the Southern Ocean, exactly in the tract of the heated continent, namely, from the south-west to the north-east. When the sun passes into the southern hemisphere, the monsoon alters its course. Winter now reigns in the mountainous and northern parts of Asia, and the heat in the lower regions is not so great. The land, in place of heating, cools the air, which flows into the warm regions of the south from the north-east in the direction of the continent, as it formerly flowed towards the north from the

¹ See Humboldt's *Political Essay on the Kingdom of New Spain*. He mentions, that at Vera Cruz the centigrade thermometer sometimes falls, owing to those northern blasts, to 0 or to 32 degrees of Fahrenheit; and that even at Mexico they sometimes, though rarely, bring down the thermometer to the freezing point.

³ Fraser's *Narrative of a Journey into Khorassan*, Appendix, p. 95.

⁴ Kinneir's *Geographical Memoir of the Persian Empire*, p. 122. It is mentioned in the Journal of a Mr Campbell, quoted by Sir J. Malcolm, that while he was at Tabreez a heavy fall of snow occurred in May; and in December and January the thermometer at night was never above zero. (Sir J. Malcolm's *History of Persia*, vol. ii. p. 509.)

Asia.

south-east. The south-west monsoon sets in about the beginning of June in all the islands of the Indian Ocean, and traverses the southern plains, until it is turned towards the west by the central mountains, and finally arrested in its progress. It is ushered in with the most tremendous thunder and lightning, with tempests of wind and floods of rain. This is the commencement of the periodical rains through all the tropical regions of Asia, which are at their height in July, and gradually abate about the end of September, departing amid thunders and tempests, as they came. Before the setting in of the monsoons there is a clear sky, with a hot parching wind, succeeded by sultry calms, under which all nature seems to droop. The rains effect a sudden and total change in the aspect of the country: the rivers are swollen, the air is pure and refreshing, the sky varied with clouds, and the earth covered with the most luxuriant verdure.¹ Such is the climate of Southern Asia, from China to the coast of Africa. But the peninsula of Arabia is not subject to the influence of the monsoons; and in place of the tropical rains, it has generally, in the mountainous parts, the winter and the spring rains.² The climate during summer is hotter than in any other part of the world, the thermometer frequently rising to 110°, and even it is said to 120°, in the coolest and shadiest parts, while dead calms prevail often without interruption for 50 or 60 days, and are succeeded, as the temperature begins to vary and the winds to resume their activity, by violent and hot blasts from the desert. The vicinity of Arabia to the African continent, by which it is sheltered from the cool breezes of the sea, while it receives the sultry air from its burning plains, is unquestionably the cause of its extraordinary heat; and it will be remarked that those violent heats extend eastward from Arabia exactly in the direction in which they are received into the lower valley of the Euphrates and the Tigris, where at Bagdad they raise the thermometer to 120° in the shade. It has been already mentioned that the progress of the monsoons to the north is arrested by the central mountains; and the elevated tract of country, therefore, which lies to the north of this barrier, namely, the kingdom of Kokaun, over which are spread the headwaters of the Oxus, Balk, the ancient Bactriana, Buckharia, and the countries west of the Indus, as far as the Hellespont, depend on the spring and the winter rains which they receive from the west.³

Western Asia has been long celebrated for the mildness and serenity of its climate, which is hot and dry, though it is tempered by the cool breezes from the mountain tracts by which it is intersected. In the northern parts, along the coasts of the Black Sea, the country is liable to excessive rains; while the southern shores of the Mediterranean are exposed to the sultry simoom blasts from the African or Arabian deserts.

Northern Asia, of which the Altai chain is the boundary, is the proper region of cold; and the severity of the climate is said to be aggravated by the vast expanse of the continent in the frozen latitudes of the north. In the interior of Asia the milder element of the ocean can have no influence on the rigour of perpetual winter; and from the Arctic Ocean to the Altai Mountains the north wind sweeps without interruption along the Siberian plains, and occasions an intensity of cold which is not experienced in the corresponding latitudes of Europe. It is remarked by Malte-Brun, that the cold increases as we proceed eastward, to such a degree, that on the coasts of Tartary, in the same latitude as France, the winter commences in

September. This intensity of cold he ascribes to several causes: 1st, To vast mountains covered with glaciers, which rise between Corea and the countries on the river Amour; 2dly, to the still greater mass of mountains which separates the Amour from the Lena; 3dly, to the thick and cold fogs which constantly overhang those frozen countries, and intercept the rays of the sun; and, 4thly, to the absolute want of inhabitants, and consequently of cultivation. There is no doubt that such causes tend to the increase of cold. They must, however, be somewhat counterbalanced by the vicinity of the Eastern Ocean tempering the severity of a Siberian winter; and the greatest degree of cold should still, therefore, be found towards the centre of the continent. On the northern shores of Asia the severity of the cold will not, as in milder climates, be counteracted by the influence of the ocean, which is either covered with solid or with floating ice. The natural coldness of the air in these countries will be aggravated rather than softened by the vicinity of these frozen seas.

Asia, from its vast extent and unequal surface, not only comprehends within its bounds the vegetable produce of the whole earth, from the low creeping lichen which flourishes on the borders of perpetual snow, to all the splendid varieties of tropical vegetation; but it presents these varieties within a very short compass. It would be inconsistent with the plan of the present article to describe in detail the animal and vegetable kingdoms of Asia. It may be therefore generally stated, that the great staples of agriculture, the alimentary plants on which man depends for his subsistence, are, in the tropical countries of Asia, rice, of which there are 27 varieties; maize, millet, and many varieties of a coarser grain called dourra; as well as other species of legumes not known in Europe. The cultivation of these nutritious grains is confined to the plains of Hindostan and the hot countries to the east. Rice or maize may be sometimes seen in Persia, or in the hot plains of Lower Syria; but agriculture in these countries generally depends on the grain of a colder climate. Persia is accordingly famed for the most excellent wheat, which is the chief food, and for barley and millet. Oats are more rarely attempted in that climate. Throughout Syria and Asia Minor, as well as Arabia, wheat, rye, barley, beans, and other grains, are chiefly sown; and in Buckharia, and generally in all the countries that lie between the Oxus and the Caspian Sea, these and other grains, with a variety of leguminous plants, constitute the chief dependence of the inhabitants.⁴ Between the 50th and 55th degrees, these grains may with care be raised all over Asia; but beyond this they cannot so well resist the severity of the climate. This is therefore the proper region of barley and oats, the cultivation of which may be extended to the 60th degree. Beyond this the powers of vegetation fail under the benumbing influence of cold; and the earth yields nothing but dwarf trees, lichens, and some species of the wild berry. In ascending the Asiatic mountains, the same varieties of vegetable produce are observed as in receding from the equator, until, at the line of perpetual congelation, all traces of vegetation disappear. But the decrease of heat in proportion to the altitude varies in different situations, according as it is affected by local and accidental causes; and though the most accurate calculations have been made on the subject by Leslie, Humboldt, and others, they are modified by local causes. Thus the limits of perpetual congelation have been fixed by Humboldt at

¹ Elphinstone's *Account of Cabul*, chap. v.

² Niebuhr, vol. ii. sect. 29.

³ Fraser's *Narrative of a Journey into Khorassan*, Appendix, p. 95.

⁴ *Ibid*, Appendix, p. 96.

15,700 feet under the equator, and 15,000 in the latitude of 20 degrees; yet Captain Webb, in his journeys among the Himalaya Mountains, observed, on the banks of the Sutledge river, which must have been at least in the 30th degree of north latitude, the finest pastures, and crops of a species of barley from which the natives make their bread, at a height of 15,000 feet, the supposed line of perpetual frost. And at a pass among these mountains, in 30 degrees of north latitude, plants were found that ripened their seed at the enormous height of 17,000 feet. In latitude 30° 25' the same traveller saw fields at the height of 11,790 feet, not only without snow, but covered with extensive fields of buck-wheat and Tartaric barley. The decrease of heat in proportion to the altitude attained appears not to be subject to any certain rule; and it would be extremely interesting to ascertain by actual observation the height at which the produce of the colder climates could be cultivated in different parts. We cannot fix either the lower or the higher limit at which wheat and other European grains could be brought to maturity among the Asiatic mountains. It is evident that the decrease of heat as we rise above the level of the sea is modified by local causes, in the same manner as when we recede from the equator; and hence the same vegetable produce is not uniformly found at the same height, any more than within the same latitudes. It is possible that in the interior mass of the mountains the cold may be greater than among the exterior ridges, and that the European grain, and the other congenial produce of a cold climate, may not on this account ripen at so high an elevation. It is mentioned by Turner, that he saw wheat in Thibet in a green state, which he was assured would never ripen owing to the severity of the climate.

Of the other plants which minister to the comfort of man, and afford valuable articles of commerce, Asia possesses great variety. The tea plant, which is exported so largely to Europe, is indigenous to China, to which its cultivation has hitherto been confined, and to which it is a source of prodigious wealth. Arabia is the native country of coffee, where it still arrives at its greatest perfection. The sugar-cane is cultivated in Hindostan, though not with the same energy and skill as in the West Indies; and also in some of the hottest parts of Asia Minor, but not to any extent. Tobacco is very generally produced in Southern and Western Asia; and the poppy plant, the great intoxicating drug of the East, is a great article of cultivation in Hindostan, and is now exported in immense quantities to the China market.¹ The vine grows to great perfection among the rocky heights of Palestine, and in the mountains of Syria, where wine of a good quality is made, and also in Arabia. Industry and skill are alone necessary to improve the advantages of nature, and to render this precious produce a valuable article of commerce. The cotton shrub, which yields so useful an article of clothing, has from time immemorial been naturalized in India, growing in Arabia, Persia, and throughout Asia Minor; and the mulberry, which affords so splendid an article of dress, is cultivated with success in Syria, Mesopotamia, and Armenia. Flax and hemp are common throughout both Southern and Western Asia, and they would grow also in Northern Asia if the inhabitants knew how to profit by the advantages of the country. Indigo is another important article, which is cultivated in India and in some parts of Syria, as well as in Arabia. The Asiatic islands have been long celebrated for various aromatic plants; and the juice which exudes from the trunks of the smaller trees is of the richest fra-

grance. Among the species of laurels which abound in the southern parts of India and Ceylon we find those which produce mace, cassia, and camphor; and, lastly, the cinnamon tree, formerly supposed to be a native of Arabia; also the clove and the nutmeg trees. The balm of Mecca is the finest of all the gums, and diffuses an exquisite perfume. Arabia has also been long celebrated for frankincense and myrrh. Asia furnishes also many plants used in medicine, as well as in dyeing, such as the castor-oil plant, the senna, the aloe, and others, which extend all over the southern parts and through Asia Minor.

In Southern Asia the forests abound with the most valuable trees, with the most durable woods, and with every variety of ornamental and dye woods. The teak tree, which grows in the woods of India, surpasses all others in hardness and durability. There are many trees which minister to the subsistence of man. All the palms, for example, distil a rich and nutritious juice; that of the sago palm, distinguished for its beauty and spreading foliage, is so thick and nutritious, that it is used in this country as a medicinal and wholesome diet. The fan palm, which grows in some parts of India, is remarkable for the breadth of its leaves, one of which is sufficient to cover a dozen of men, and two or three to roof a cottage. The bread-fruit tree, which grows in India, yields a farinaceous fruit resembling bread prepared from grain. All the common fruit trees of Europe are also found in the hilly parts of India. Asia Minor and the banks of the Euphrates abound in the myrtle, the laurel, the turpentine, mastic, tamarind, cypress, sycamore, and other trees. The oriental plants are numerous in Persia; and in the Syrian mountains the oak and the cedar, celebrated in ancient times, grow to a great height. In the northern countries of Asia the trees most prevalent are the oak, the ash, the elm, &c.; and still farther north there is the dwarf birch and the mountain willow; also the pines and the firs, which rear their tall heads, and spread over the scenery their permanent hue of dark green. The strong and glutinous liquid which exudes from these northern trees is converted into tar, pitch, and turpentine, and becomes a valuable article of commerce, useful for many purposes.

All the most delicious fruits are raised in the tropical countries of Asia. Those most celebrated in India are the guava, the jambo, the mango, and the pine-apple; many others might be raised if garden-cultivation were attended to as it might be in that country. Syria, Palestine, the banks of the Euphrates, and Persia, are famous for the variety of their fruits, and produce abundantly pomegranates, oranges, lemons, almonds, peaches, figs, quinces, olives, walnuts, and melons of all sorts. In the neighbourhood of Damascus all the fruits of Europe arrive at maturity; and near the Caspian Sea there are whole forests of chesnut trees. The date tree, the fruit of which is in many parts the chief subsistence of the inhabitants, grows in Persia, Mesopotamia, Arabia, Syria, and Palestine. In the higher parts of these countries other fruits are to be found, namely, the apple, the pear, the cherry. In Northern Asia horticulture is little practised; and, excepting wild berries, few other fruits are to be seen in its desert and inhospitable plains. Flowers of all sorts, in the most splendid profusion and variety, and of the richest fragrance, adorn the country in Southern and Western Asia, and give it the appearance of a flower-garden. On such a subject, however, which presents so wide a field of inquiry, we cannot enter into details, which would hardly prove satisfactory to the general reader, and still less to the man of science.

¹ Minutes of Evidence before Committee of House of Commons on China Trade.

Asia.
Animals.

The desolate tracts of thick jungle and dense forest which abound in Asia afford extensive cover for wild animals, which are accordingly found in great numbers, and comprise all the known *genera* of the globe. The lion is found in Persia, Mesopotamia, on the banks of the Tigris and Euphrates, and was formerly known in Asia Minor, but has now either entirely disappeared, or is rarely seen. It was not supposed that this formidable animal haunted the forests and jungles of India. But of late lions have been seen in great numbers in the north of India, in Guzerat, and in the province of Delhi, to the north of this place.¹ The tiger is a native of Asia, to which continent he exclusively belongs, having never migrated into the other regions of the globe. He is spread over all parts of Southern Asia, from the islands of the Indian Ocean, where he exists in amazing power and ferocity, to the great ridge of the Himalaya Mountains.² His progress northward is checked by the increasing cold; yet is he found in some of the higher regions, where ice is seen during the winter. It is certain, however, that he is a native of a hot climate; and it is probable, therefore, that when he feels the approach of winter, he will retire from the cold of the high country into the warmer and lower valleys of the south. Tigers are seldom seen in the countries westward of the Indus, though they may occasionally stray from their native haunts along the west of that river into the mountain tracts of Belochistan.³ The tiger is not found in Persia, Arabia, or in any part of Africa, though it is quite certain that the country is quite congenial to his constitution and habits, and that if he could once reach it he would quickly propagate his race through its deep forests. Yet the lion reigns supreme in the woods of Africa, while the tiger is the lord of the Asiatic jungles. It would be curious, if we had materials for such a speculation, to trace the distinct regions of the globe which are occupied by the various animal and vegetable tribes. Plants, we know, are transported from the countries in which they are indigenous, and flourish in another soil and climate equally congenial; and, in like manner, the animals of one country have been transported with equal success to other countries, where they have multiplied. The wild and ferocious animals it is the object of man to destroy rather than to increase; and they would therefore receive no aid from him in their migrations from one region to another. Hence we find that those countries which are widely separated, and which present no practicable communication for animals, have each its own peculiar and distinct class. America has an entirely different race of animals from Africa or Asia; while the animals that are found in the islands or continent of Australasia (New Holland), resemble those of no other quarter of the world. The zoology of Asia and Africa, from their vicinity, and from the comparatively easy communication between them, does not present such diversities; yet it is remarkable, that while the lion is common over all Africa, the tiger has never yet been seen; while in Asia it is just the reverse, the tiger, and not the lion, being the more common of the two. There can be no reason, we should imagine, why the tiger should be confined to Asia, while there are other countries equally suited to his habits, except that, being indigenous in the regions of Eastern Asia, he has never been able to cross the barrier of mountains and deserts by which these regions are separated from Persia on the west. Beyond

the western banks of the Indus the country is mountainous and impassable, and the climate extremely cold; the ridges from the Himalaya Mountains extending southward nearly to the sea, and the country beyond being merely a narrow strip of hot and sandy desert. Beyond this, farther to the west, extensive deserts are found, destitute of water and of all traces of vegetation, which would as effectually oppose the passage of wild beasts as the trackless ocean which divides Africa and America, and leaves to each its own class of indigenous animals. The other wild animals of Southern Asia are leopards, hyenas, jackals, tiger-cats, wild boars, antelopes, elks, red and moose deer, foxes, hares, mungoses, ferrets, porcupines, &c. All these are to be found in the southern plains of Asia. The hyenas, wolves, jackals, and bears, abound in some of the hilly tracts, and in the mountains of Belochistan and the other countries to the west of the Indus. The three first make dreadful havoc among the flocks. The same animals are found in Persia, Mesopotamia, in Asia Minor, and in Palestine; and it is said that the lion is occasionally seen on the banks of the Jordan. The ounce is a formidable animal in these countries and in Syria, and is sometimes mistaken for the tiger. The timid zebra is found in the depths of the Persian forests.⁴ The wild dog is common in Northern India, in Belochistan, and in all the mountainous countries to the east of Persia. It is a large and powerful animal, and extremely ferocious. They hunt in packs of 20 or 30, and frequently seize a bullock, which they kill in a few minutes.⁵ The bones and remains of tigers, supposed to have been destroyed by the combined attack of these animals, are also sometimes found in the woods of Northern India.⁶ The wild ass is a native of Persia, and is remarkably wild, and fleet in its movements. It is also common in the northern mountains of India, and in the countries to the west of the Indus. The wild sheep and the wild goat are common among the mountains.

Of the domestic animals, the elephant claims the pre-eminence, being unequalled by any other animal for the purposes of draught. This animal is confined to the southern countries of India, where the climate is hot, being seldom seen in the mountainous tracts towards the north. The camel is used for domestic purposes over a far wider extent of country than the elephant. This animal is of two species, the one with two humps, and the dromedary with only one hump; and it is domesticated all over India and the mountainous countries to the north of the Himalaya ridge, in Balk or Bactria, in Buckharia, in Tartary, in all the countries bordering on the Caspian Sea, even in the southern provinces of Europe, in Persia, Asia Minor, and the countries bordering on the Black Sea, and in the Arabian deserts. The two-humped camel is a remarkably useful animal for burden, being heavy in his make, with enormous bones, shaggy coat, amazing strength, and incredible patience of fatigue and of thirst. The dromedary is chiefly used for travelling, and its valuable quality is swiftness, by which, joined to its capacity of enduring hardship, it is qualified to travel at an incredible rate for many successive days. In all the low countries, especially in the dry and sandy tracts, such as Arabia, Syria, &c. the dromedary is employed. The two-humped camel is a native of the high countries in the neighbourhood of the Oxus and the Jaxartes, where it is

¹ Elphinstone's *Account of Cabul*, p. 141.

² See Pottinger's admirable account of the countries of Belochistan and Sind, chap. vii. which is replete with interesting information. The journey of this officer and of Captain Christie, from India to Persia, through these wild tracts, inhabited by hordes of robbers, may be considered a most perilous and honourable achievement, worthy of the greatest travellers.

⁵ Bishop Heber.

⁶ Bishop Heber.

still chiefly used. So large a portion of Asia is occupied by vast plains and wastes of sand, that its interior intercourse must be maintained by land journeys. But without the aid of the camel it would be impossible to traverse extensive deserts, destitute both of food and water; and in those arid countries such an animal, which has been truly called the *ship* of the desert, is the most valuable gift which Providence could bestow.

The other domestic animals of Southern and Western Asia are horses, mules, asses, buffaloes, black cattle, sheep, goats, &c. Arabia may be considered the native country of the horse, in which he arrives at the highest perfection, and combines all the most estimable qualities of symmetry of form, fineness of skin, fire, docility of temper, fleetness, and hardiness. It is chiefly from the Arabian breed that the horses in other parts of the world have been improved. In Persia the horses are neither so graceful nor so swift as those of Arabia, being high, with long legs, spare carcasses, and large heads; but they are highly prized by the inhabitants for their extraordinary capacity of enduring fatigue. To the east of Persia, at Herat, the breed of horses is fine; also on the banks of the Indus and its tributaries; and in the higher regions of Balk and Buckharia they are excellent and numerous, and are exported in great numbers to Hindostan.¹ The mule and the ass, all over India, are miserable animals. The mules are of a better quality in the Punjaub, on the upper course of the Indus, and they improve still more farther west. In the countries west of the Indus they are superior to those in Hindostan, and in Persia there is still a finer breed. But the mule of the east is inferior to that of England. The ass partakes of a similar improvement in his progress west, and is a far finer animal in Western Asia than in Europe. In Syria, Palestine, and generally in Asia Minor, he is distinguished by agility, fire, and patience of fatigue, and ranks in the first class of domestic animals. Buffaloes are found in the hot plains of Asia, as well as in the mountainous tracts; and the oxen which are used in the plough have all a hump on their backs. The wealth of the pastoral tribes who rove about in the western plains of Khorassan, and in the hilly tracts of Afghanistan, consists chiefly in sheep, which have tails a foot broad, and composed entirely of fat, and in other respects resemble the English sheep, being better and handsomer than those of India.² Goats are common all over Asia, especially in the mountains, where there are some breeds with curiously twisted horns; and they are by no means scarce in the plains.

In the northern parts of Asia, and in the high mountain tracts, a different class of animals is to be found. These cold regions are not distinguished by the same profusion of animal life as the tropical countries. The beasts of the forest decrease in numbers, in size, and also in fierceness; and the wolf, the bear, and the wild boar, are the only ferocious animals which thrive in these northern climates. In advancing on the desolate plains of Siberia to about the 60th degree of N. lat., we find the cold still taking effect on the animal as on the vegetable creation, and the living creatures as well as the plants and trees stunted in their fair proportions. Beyond this limit a different order of animals appears, protected against the severity of the climate by a thick covering of fur, which is sought after as a rich article of dress in more opulent countries. These animals are accordingly hunted for their skins, which constitute the great staple article of trade in Northern Asia. In the Arctic regions the bear

seems to form the only exception to the diminished grandeur of the animal creation. This animal, nourished in the regions of perpetual snow, acquires a larger size and far greater power and fierceness than in southern climates. The domestic animals of the northern and mountainous countries of Asia are of a less imposing appearance, and not nearly of the same strength as those in the lower valleys of the south and west. In the high and cold plains of Central Asia the camel is no longer used as a beast of burden, nor in the northern parts of the continent. Thibet, Tartary, and the plains to the north of the Altai Mountains, are mostly inhabited by Tartar tribes, whose wealth consists in their cattle, which not only furnish them with food, clothing, and shelter, but are also used as beasts of burden, and in the labours of agriculture. The yak of Tartary, or the bushy-tailed bull of Thibet, seems to supply the place of the camel in these mountainous countries. This animal is about the size of an English bull, of great strength, and is reckoned a valuable property among the itinerant hordes of Tartars, to whom it affords the means of easy conveyance, of clothing, and shelter for their tents, from the prodigious quantity of long flowing glossy hair on its tail, and finally of subsistence from its milk and flesh. In those mountains is also found the musk-deer, which delights in the most intense cold, and of which the musk, a secretion by the male, affords a revenue to the government, as well as a valuable article of trade. Here also, on the highest mountains, amid ice and snow, is the Cashmere goat, the wool of which affords the materials of the finest shawls.³ Wild horses are seen in the high plains of Thibet; and the breed of sheep, a peculiar species of which is indigenous to the climate, is of great value. They are nourished on the short and dry herbage of these exposed plains, and serve for subsistence to the inhabitants, as well as for beasts of burden. The wild and extensive plains of Tartary are inhabited by pastoral tribes, who depend in like manner on their herds. On the southern side of the Altai Mountains we find the same tribes of wanderers, most of them the scattered remnants of the Tartar nations who had formerly so deep a share in the great revolutions of Asia. All these tribes subsist chiefly by pasturage. Near the Ural Mountains some live chiefly by hunting or ensnaring the elk and other wild animals for their furs. Among those who are shepherds, sheep and horned cattle are found; while the hunting tribes have scarcely any domestic animals. In all these countries the wolf and the bear are known to abound. In the rigorous climate farther to the north, where the cattle are stunted in size, and can scarcely subsist, their place is supplied by the rein-deer, a species peculiar to this rigorous climate, and most valuable for all domestic purposes, whether for draught or for subsistence. During part of the year the inhabitants of those desolate countries subsist upon its flesh or milk, its skin furnishes them with the chief part of their dress, and its horns with such domestic utensils as they require. The dog is also trained to draw the sledge.

The feathered race in Asia includes almost every known species. In the southern parts are found all the tropical birds, distinguished by the most beautiful plumage, and some of them uttering sounds that have a resemblance to the human voice. Here are also found some of the largest and rarest birds,—the ostrich, the cassowary, and in the Himalaya Mountains the condor, one of which, shot by a British officer, is stated by Bishop Heber to have measured from the extremity of one wing to another the enormous length of 14 feet. The other birds are

¹ Elphinstone's *Account of Cabul*, chap. vi.

² *Ibid.* p. 143.

³ Turner's *Embassy to Thibet*, p. 186.

Asia.

eagles, kites, vultures, magpies in the higher countries, hawks, crows, wild geese and ducks, flamingos, herons, bustards, florikens, rock pigeons, lapwings, storks, plovers, snipes, quails, partridges, different species of the ortolan tribe, and almost all the other small birds to be found in similar climates. In Northern Asia the feathered creation is nearly the same as in Europe.

The principle of life, which is so active throughout the torrid zone, and produces quadrupeds of the most enormous size, is also visible in the magnitude and numbers of the reptile tribe, many of them armed with the most fatal poisons, all of them odious to the sight, and some, such as the boa constrictor, attaining the length of 30 feet, and of such prodigious muscular strength as to coil round and crush the largest animals to death. The influence of cold is adverse to the growth of these serpents, which are not found in Asia to the north of the Altai Mountains. The shark, which is found in all warm climates, haunts the tropical seas of Asia; and the crocodile, which is a different animal from the alligator of America, though equally powerful and ferocious, infests the rivers. All sorts of insects, namely, mosquitoes, ants, gnats, flies, &c. most of them noxious and destructive, swarm in the torrid regions of this continent. During the short summers of Northern Asia the musquito and other insects abound in the woody tracts of Siberia, insomuch that near the Ural Mountains the peasants burn constant fires before their cottages, as a defence against their attacks.¹ But the locust, which is peculiar to certain parts of Asia, is the most mischievous of all these winged creatures. They light upon a country in a cloud which darkens the air, and leave nothing green behind them; fields sown with grain being utterly laid waste, and trees stripped of their leaves, and of all power to ripen their fruits. They overspread the country with an appearance of blackness for many miles; and when they are driven by the winds into the sea, their dead bodies cover the shore in heaps. These destructive animals appear occasionally in the countries to the north and west of the Indus, in Belochistan, in the desert tracts of Khorassan, and in Persia.² They are sometimes seen in Arabia in countless swarms; and frequently to the north of the Altai Mountains, at the sources of the Irtisch, whence they extend their destructive flight as far as the Crimea and the southern provinces of the Russian empire.³

Historical sketch of the Asiatic nations.

Asia has been subject to more awful revolutions than any other part of the world. Though it was at a very early period the seat of flourishing kingdoms, it was soon desolated by war. Its wealthy cities, sacked by their conquerors, fell into decay and ruin; and many of its countries, once civilized and populous, now languish in desolation from violence and misrule. The mighty revolutions which have shaken this continent form an interesting subject, on which volumes might be filled. All that we can propose is a historical sketch of the great leading events which distinguish the annals of Asia, with a brief notice of the various nations which have flourished, or are now to be found within its limits.

Nineveh, Babylon.

The early history of Asia, like that of all other countries, is lost in antiquity; and the obscurity is but slightly dissipated by the indistinct accounts which we receive from the Greek historians, and the brief notices in the sacred volume, of the Assyrian and Babylonian empires. The Assyrian empire appears to have been established by Ninus or Belus, the Nimrod of the Scrip-

tures, who, we are told, began to be mighty on the earth, and the beginning of whose kingdom was Babel or Babylon.⁴ It was farther enlarged by the renowned queen Semiramis, who carried her arms into India, and extended her sway from the Euphrates to the Indus. The great city of Nineveh had its origin about the same time as Babylon. Sardanapalus was the last king of the Assyrian empire, which subsisted, according to some historians, 1300 or 1450 years. But Herodotus fixes its duration, on what authority does not appear, at 520 years. Sardanapalus was dethroned by Arbaces, governor of Media; and on the ruins of this kingdom two others arose, namely, the empire of Nineveh, under Arbaces, formerly governor of Media; and the empire of Babylon, under Belesis, the former governor of that city. Nineveh was the capital of the former empire, which embraced the countries on the upper course of the Euphrates and Tigris, and also the country to the east. To the empire of Babylon belonged Chaldea, including the lower valley of the Euphrates. This revolution took place in the 747th year before the Christian era, and in the 7th year after the building of Rome.⁵ Some are of opinion that three kingdoms arose on the ruin of the Assyrian empire; but this is generally considered to be an error, the two supposed kings, Arbaces and Tiglath-Pileser or Ninus the younger, being the same person.

It is conjectured that the cities of Babylon and Nineveh were begun about 100 years after the flood, or in the year of the world 1771. At the same time we have no data for fixing with accuracy the chronology of this early period; and the different opinions held by most learned writers sufficiently mark the uncertainty of history in those ancient times. It would appear, however, that the fertile countries of Asia were rapidly overspread with inhabitants. Abraham, according to the Jewish chronology, was born 290 years after the flood; and in his time we hear of the cities of Ur of the Chaldees and of Damascus, besides others which had arisen in the valley of the Jordan, the inhabitants of which devoted themselves to commerce and agriculture; and we are told that this tract of country was well watered, and was even as the garden of the Lord, like the land of Egypt.⁶ But from the incidents related, it would still appear, that excepting the plains of Jordan, which were brought under cultivation, the country was occupied by pastoral tribes. Abraham, when he proposes to separate from Lot, in consequence of the strife of their herdsmen, tells him that the whole land is before him; and he gives him his choice of either going to the right or to the left with his flocks; an arrangement which was scarcely consistent with a high state of cultivation, and which could not have been afterwards proposed when the country was fully peopled.

The posterity of Abraham, who were settled in Egypt, having greatly multiplied in the course of 450 years, were at last permitted to depart; and having crossed the Red Sea, they pursued their triumphant march to the land of Canaan, expelling or extirpating the inhabitants. Thus was laid the foundation of the Jewish commonwealth, which became, in the prosperous reigns of David and Solomon, one of the most flourishing empires of Asia, extending on the east as far as the Euphrates, and having ports both on the Red Sea and in the Mediterranean.

Western Asia was in this manner occupied between the 7th and 8th centuries before the Christian era by the

great Assyrian empires of Nineveh and Babylon, and by the kingdom of Israel. The limits of the first two to the east and west are not accurately defined. The Assyrian monarchs sometimes carried their victorious arms eastward into Bactriana and to the Indus; but whether they ruled over these conquered countries is uncertain. Their empire, it is probable, extended westward into Asia Minor. On the shores of the Mediterranean, Tyre, with several other flourishing cities, had at a very early period attained to wealth and splendour. Arabia was, as at this day, inhabited by wandering tribes of shepherds and robbers; and other tribes of the same character had spread themselves abroad on the northern plains.

The great ruling powers of Asia were engaged in continual wars; and the Medes, having thrown off the Assyrian yoke, contended with the others for the dominion of the world. Having joined the Babylonians, they invaded the kingdom of Nineveh, already broken by repeated assaults, and took and burnt the capital, thus bringing to an end this great and ancient empire, which had flourished nearly 1500 years, and 135 years after its separation from Babylon. The rise of these formidable empires on the Euphrates was portentous to the peace and safety of the neighbouring states. The kingdom of Israel, weakened by the revolt of the ten tribes, was accordingly invaded by the Assyrian armies. Samaria was subdued; and Jerusalem, overpowered by the victorious armies of Babylon, was taken and utterly destroyed, and the people carried away captive. The overthrow of the Jewish kingdom took place 588 years before the Christian era.

Persia did not at this period (A. M. 3405, B. C. 599) include more than one province of the extensive country since known under that name, nor did it contain more than 120,000 inhabitants. But it was soon after united with Media, under the vigorous rule of Cyrus; and that warlike monarch enlarged his dominions on every side. Having subdued the Lydians under Cræsus, the allies of the king of Babylon, and the other adjacent states in Asia Minor, he thence proceeded into Syria and Arabia, which he also subjected; and extending his conquests from the Ægean Sea to the river Euphrates, he finally advanced against Babylon, and, having taken that great city, put an end for ever to the Assyrian empire, which had been renowned from the earliest period of the world. The kingdom of Babylon had subsisted, after its separation from Nineveh, 209 years. It was overthrown 50 years after the destruction of Jerusalem, and 540 years before the Christian era.

Persia continued to rule over Asia for above 200 years, when its power was overthrown by Alexander the Great. His extensive conquests were divided among his generals, who renewed the strife for dominion which had been for a time extinguished by the ascendancy of Persia. Amid these contentions Parthia and Bactriana in the east rose to the rank of independent states. The Roman armies entered Asia about 200 years before the Christian era, and subduing all opposition, they finally established the dominion of Rome from the Hellespont to the eastern boundary of the Euphrates. By the decided triumph of this great power mankind obtained a fresh respite from the calamities of war. It was the first care of the Romans to cement by policy what they had gained by arms, and to establish order and tranquillity in all parts of their widely extended territories. From this period, accordingly, may be dated the commencement of that brilliant era of prosperity and repose enjoyed by this portion of Western

Asia for nearly 700 years, the time which elapsed from its final conquest by the Roman armies under Pompey to its subjugation by the Saracens in the 638th year of the Christian era. The people, profiting by the singular felicity of their lot, devoted their attention to commerce and the arts of peace, and attained to a high degree of wealth and refinement. All the civil institutions of society flourished; science and literature were cultivated; and mankind, basking in the sunshine of domestic repose, seemed to enjoy the illusion of perfect happiness. It is estimated that 500 populous cities covered the face of the country. These were adorned with magnificent temples and other splendid monuments of art; and some of them, such as Pergamus, Smyrna, Ephesus, &c. and especially Antioch and Alexandria, rivalled in extent and magnificence the majesty of Rome itself.¹

After an interval of 500 years, the Persian monarchy Hindostan was revived under the dynasty of the Sassanides.² In and China. Eastern Asia the splendid and populous empires of Hindostan and China, though imperfectly known in Europe, had flourished for many centuries. The origin of the Hindoo power is buried in a remote antiquity. The first authentic notice of this mild and pacific people was brought to Europe by the officers who accompanied Alexander's expedition to India. Prior to the era of the Mahometan conquest in the year 1000, the Hindoos possess very imperfect materials for their history.³ Hindostan comprehended then, as now, the extensive country bounded by the Indus on the west and the Ganges on the east, though we know but little of its boundaries or internal state. The origin of the Chinese, as of other nations, is hid in obscurity. They claim their descent from a very high antiquity, their history going back by tradition to the remote period of 40 centuries, and for 2000 years their annals are verified by the testimony of contemporary historians. It is quite certain, indeed, that long before the Christian era they had emerged from the barbarism of pastoral life, and were devoted to agriculture and commerce; that they had acquired wealth and prosperity, and were thoroughly instructed in all the arts and refinements of civilized nations.

The historical sketch which we have given above includes only the civilized portion of India. But a great proportion of her population were in ancient times shepherds, who dwelt in tents; and it is the more necessary to attend to the distinction between these two classes, as it will be found to illustrate the political history of Asia, and those stupendous revolutions which have not only shaken this continent to its centre, but have been extended to the remotest parts of the world.

It has been already mentioned that the vast table-land of Central Asia, though containing large tracts of desert, is nevertheless interspersed with fertile and well-watered valleys, which produce abundance of pasture; and the immense plain to the north of the Altai Mountains, which extends over the whole breadth of the continent, from the Eastern Ocean to the Volga, is one continued meadow, affording subsistence for innumerable herds of cattle. In all ages, accordingly, those plains have been inhabited by wandering tribes of shepherds, rude, ferocious, and delighting in war. It is finely observed by the Roman historian, that "the pastoral manners, which have been adorned with the fairest attributes of peace and innocence, are much better adapted to the fierce and cruel habits of a military life." Such, accordingly, has been the character of all the pastoral nations. They have been always

¹ Gibbon's *Decline and Fall of the Roman Empire*, chap. ii.

² Sir J. Malcolm's *History of Persia*, chap. iv.

³ Rennel's *Memoir of a Map of Hindostan*.

Asia.

addicted to violence and plunder; and their predatory expeditions, whether for the plunder of individuals or of empires, have been invariably conducted with the same fierceness and cruelty. In a pastoral state every man is a soldier, and he is trained to war by his daily occupations. He is hardened in his body by continual exercise and exposure to the weather; in hunting the wild animals of the forest, he acquires skill in horsemanship and in the use of all warlike weapons; and in the perpetual migrations of his tribe, which must be carried on with the same order as the march of an army, he is trained to vigilance and discipline. These wandering barbarians were, besides, engaged, as may be easily supposed, in continual wars with each other. Here, as elsewhere, the usual scarcity of subsistence and of room would soon be experienced with the progress of population. Disputes would thence arise, and fierce contests, which would only terminate with the destruction of one or other of the contending tribes. Of such obscure wars we have no accurate account, though it is certain, that from time immemorial the work of mutual slaughter has been going on in the interior of Asia; and it is obvious that those vast multitudes, if they had been united under some able leader, who could compose or crush all domestic dissensions, might, in place of wasting their strength in intestine strife, have directed it against the civilized portion of the earth, where wealth presented a tempting prize to barbarian cupidity; and, accordingly, this was precisely the calamity by which mankind were at length overtaken. The world was to be disturbed by a conflict, not as heretofore between improved states, but between barbarism and refinement. The question was now to be decided, whether polished nations or barbarians should rule the world; whether literature, science, the arts, the improved institutions, and the whole order of civilized society, should be broken up and buried under an overrunning flood of savage hostility. From the earliest times the countries of Asia Minor, and some parts of Europe, were subjected to the irruptions of barbarians; but no permanent conquest was ever attempted, and the invaders were in general quickly repelled. Asia Minor was defended against the inroads of the Scythians by the Persian monarch; and Rome, in the lion-like vigour of her growing strength, quickly shook off such unequal adversaries. Whether, however, from the increasing population of the Asiatic plains, or from the greater political union of the different tribes, those attacks were renewed with more vigour than ever; and at times the mighty mass of population over the whole breadth of the continent seemed to be agitated by one movement; and, according as the impulse given was to the east or to the west, the kingdoms of Europe or the empires of Hindostan and China were swept by the tempest of invasion. Those formidable expeditions were attended with various results. In those states which were vigorously ruled, the discipline and tactics of civilized warriors proved an overmatch for the untutored valour of barbarians. But, on the other hand, when the people, enervated by ease and luxury, neglected the study of war, and trusted for safety to a mercenary force, the country was overwhelmed by its barbarian conquerors. The Chinese empire was overturned about 200 years before the Christian era, by an irruption of the Huns; the fertile countries on the banks of the Oxus, and of the Jaxartes as far as the Caspian Sea, which had attained to wealth and prosperity under the Macedonian kings, and had ever since been cultivated like a garden, were reduced by the white Huns,

and under their sway Carisme, Buckharia, and Samarcand became the seats of industry and of flourishing manufactures, and the great marts of the Indian and European commerce; while the Roman territory in the west was repeatedly assailed, and finally overturned, by hosts of barbarians, who had quitted the crowded plains of Asia in quest of settlements to be won at the point of the sword.

It was about the middle of the 7th century that the Mahometan power emerged from the Arabian deserts; the Mahometan power emerged from the Arabian deserts; and the shepherds of those burning plains, inflamed by religious enthusiasm and the love of plunder, were equally formidable in war with their brethren of the north. Of all the invaders who, in this unhappy period, desolated the world, the Arabian tribes were the most fierce and cruel. Their religion enjoined the blindest intolerance; they were commanded to propagate their faith by the sword; and it was accounted a merit in a true believer to shed torrents of Christian blood. The track of Mahometan invasion was accordingly marked by the ruin of peaceful cities and by unsparing slaughter. In the course of two years the plain and valley of Syria was subdued by the Arabs or Saracens, whose conquests were soon extended over Asia Minor in the west and Persia in the east; and the country of Transoxiana, or the fertile plains lying on the Oxus and the Jaxartes, were, after several severe battles, reduced under the power of the caliphs, whose authority, a century after the flight of Mahomet from Mecca in the year 662, extended in Asia about 200 days' journey from east to west, from the confines of Tartary and India to the shores of the Hellespont, and in Europe as far west as the Atlantic Ocean.

The dominions of the Arabian princes, in their widest extent, were divided into provinces, under subordinate governors, who owned themselves the servants or slaves of the caliph at Bagdad, their temporal as well as spiritual ruler. In the decay of the supreme power, those rulers, under the forms of the most abject submission, had acquired independence; and the caliph remained at Bagdad the vain object of outward homage, while he was inwardly despised. The Persian kingdom was also detached from their dominion, being usurped by a new dynasty, and was extended from the Caspian Sea to the ocean. This dynasty, as usually happens in disorderly times, was supplanted by two families, who, making a division of the kingdom, ruled, the one over Khorassan, Seistan, the high plains of Balk on the northern side of the great Himalaya ridge, and the countries of Transoxiana, with the cities of Buckharia and Samarcand; and the other over the southern provinces of Persia, as far as the Persian Gulf, namely, Irak, Fars, Kerman, Khusistan, and Laristan. These families appear to have ruled in Persia for 125 years, namely, from 874 to 999. They were overthrown by the Turkish princes of the line of the Gaznevdes, the founder of which was Subuctageen or Sebecktagi, who, from a common soldier, rose to the rank of a petty prince, and fixed his residence at Ghizni. His dominions consisted chiefly of the tract of country which, after the division of Alexander's empire, composed the kingdom of Bactria, namely, the countries lying between the Caspian Sea and the Indus, and near the source of the Oxus. He invaded Hindostan, subdued Northern India and the province of the Punjab, and rendered the princes of the countries tributary to the princes of Ghizni.¹ His son Mahmoud or Mahmud, who reigned in Persia about 1000 years after the birth of Christ, was still more famous for the extent of his conquests. He had extended his empire northward by the reduction of Buckharia; and he now determined, in the

¹ Sir J. Malcolm's *History of Persia*, chap. vii.

Asi true spirit of Mahometan intolerance, to wage a holy war against the idolaters of Hindostan. At this period the Mahometans had effected no permanent settlement in Hindostan. The people were purely Hindoo, without any admixture of foreign manners; and the whole country along the east side of the Indus to Cashmere was ruled by a prince of the Brahmin race, and between whom and the kings of Delhi, Agimere, Canoge, and Callinger, a confederacy was now formed against the common enemy of their country and religion.¹ Mahmoud entered Hindostan in A. D. 1000, and having defeated the armies of the confederate kings, he reduced the province of Moulton. Eight years afterwards he penetrated into the heart of India, where his farther progress was opposed by the confederated princes of the country, from the Ganges westward to the Neerbuddah. But the fanatical invader was still victorious, and his progress was signalized by rapine and slaughter. The idols were all broken to pieces, the temples, many of them of the most beautiful architecture, were pulled down, and an immense spoil was carried away. In the course of his twelve expeditions into India Mahmoud extended his conquests to the Ganges; and when he died in 1028, his territories were of great extent. The annals of those disorderly times afford no very accurate data for ascertaining their exact limits, which are variously stated by writers of great authority. According to Major Rennel, the empire which he established comprehended the eastern, and by much the largest part of Persia, and extended nominally from the upper and western course of the Ganges to the peninsula of Guzerat, and from the Indus to the mountains of Agimere in Northern India.² Sir J. Malcolm assigns Georgia and Bagdad for its limits on the west and south-west; Buckharia and Cashgar on the north and north-east; and Bengal and the Deccan, as far as the Indian Ocean, to the east and south-east. But though a large portion of Hindostan was at this time overrun by the Mahometan armies, it was only the Punjaub, or the country of the five rivers, that was entirely reduced under any regular government, the other parts of the country being merely occupied by troops.

Turkish tribes. The empire of Mahmoud declined after his death, owing to divisions and civil wars, but chiefly to the rise of the great Tartar or Turkish tribe of the Seljooke, so called from the name of their renowned chief Seljook, who, being banished by his khan or chief from Turkestan, passed the Jaxartes with his numerous followers, and settled in the plains of Buckharia, in the neighbourhood of Samarcand, where he embraced the Mahometan religion. It is only when those barbarous hordes emerge from the desert, and come into contact with civilized life, that we obtain any clear account of their migrations and history. Their contests with each other, and their obscure wanderings in the interior, are not chronicled among themselves, and are seldom known to other nations. Hence we have rarely any clear data for tracing their origin, or their early conquests, or the consolidation of many tribes into one great nation. It is certain, however, that the vast population of Asia, agitated by internal tempests, has been always violently driven on the great empires of China and Hindostan, or on those of Persia and Rome, and has either made a breach, or, if repelled, has assailed the civilized world at some other more vulnerable point. China has been in all

Asia. ages an object of attack; and it is generally believed that the Turks, and especially that tribe of them under Seljook, had been driven by the Chinese and a tribe of Tartars from the high plains of Asia, a short time before they sought refuge in the provinces of Transoxiana. They were living near the territories of Buckharia when they first attracted the notice of the Sultan Mahmoud, the founder of the dynasty of the Gaznevites, who had advanced into Buckharia with his army, and was so impressed with the fine military qualities of their chief, the son of Seljook, that he induced them to cross the Oxus and to occupy the country of Khorassan.³ He had soon reason to repent of this fatal error. Like all those wandering hordes, the Turkmans or Turks were shepherds or robbers. They either molested the neighbouring states by petty inroads, or, with the whole united force of the nation, they practised robbery on the great scale, seizing on kingdoms and despoiling nations. The first emigration of these eastern Turkmans is generally fixed in the 10th century. They became formidable to Mahmoud, and more especially to his successor Massoud, who, from inability to resist their progress, was forced to grant them lands. He was afterwards defeated by them in a general battle; and the victorious Turks, under their leader Togrul Beg, whom they had now elected king, invaded Khorassan, and finally expelled the Gaznevites, the descendants of Mahmoud, from the eastern provinces of Persia. They fled eastward towards the Indus, and established the Ghiznian empire in the south-western provinces of India. This empire was maintained with various success till about the year 1184, under the Ghiznian emperors.⁴ It is difficult to give any accurate view of its limits, which in such turbulent times would naturally vary with the fortune of war. They appear to have embraced the eastern parts of Persia, the mountain country of Cabul or Afghanistan, and the Indian provinces of Lahore and Moulton. The Ghiznian dynasty was superseded by that of the Afghan or the Patan emperors, who completed the conquest of the greatest part of Hindostan Proper about the year 1210. Togrul Beg hastened to improve his victory over the Persian monarch. Turning his arms to the west, he invaded Irak, in the centre of Persia, and advancing westward of the Caspian Sea into Azerbaijan, the ancient Media, he made his first approaches to the confines of the Roman empire. He afterwards proceeded to Bagdad, and by his conquest of that place he gained possession of the person of the caliph, who was treated with the most profound veneration. His successors Alp Arslan and Malek Shah extended the empire transmitted to them by Togrul Beg. They subdued the fairest portion of Asia. Jerusalem and the Holy Land, which flourished under the mild sway of the caliphs, was taken and pillaged by one of the lieutenants of Malek Shah; and it was the vexation and rapine to which the Christian pilgrims were exposed in their journey to Jerusalem under the barbarous rule of the house of Seljook, that inflamed the indignation of the Christian powers, and gave rise to those wild and warlike expeditions for the recovery of the Holy Land, known under the name of the Crusades. The empire of the Seljookian Turks extended, under Malek Shah, from Egypt and Syria to Buckharia, which he conquered as far as Samarcand and Kharisme. He received homage from the tribes beyond the Jaxartes, and compelled the

Asia.

sovereign of Cashgar to offer up public prayers for his prosperity, to strike money in his name, and to pay him an annual tribute.¹

Internal wars.

From this period till the invasion of Zinghis or Ghenghis Khan, which is 110 years, namely, from 1092 to 1202, Asia was convulsed by foreign and intestine wars. The death of Malek Shah dissolved the unity of his extensive empire, in which three new dynasties arose; while in many cases the provincial governors contended for supreme authority, and harassed the country by their mutual wars. It was during this era of division and weakness that Asia Minor, which was ruled by the dynasties of Iconium and Aleppo, was invaded by the hosts of the European crusaders, who rapidly subdued the country, took the holy city of Jerusalem, and extending their conquests over the hills of Armenia and the plains of Mesopotamia, founded the first principality of the Franks or Latins, which subsisted 54 years, beyond the Euphrates. Those European invaders retained possession of Asia Minor and of Syria for nearly 200 years. Exhausted at length by a long series of sanguinary services, and not receiving reinforcements from home, they were finally driven from all their conquests by the coalition of the Turkish powers.

The Turkish dynasty of the Seljooks continued for 158 years, or 215 years if we reckon from the time that the tribe first emerged from the desert under its leader Seljook. The sultan of Carisme or Kharisme, who ruled over the country situated between the Oxus and the Jaxartes² with delegated authority, profiting by the distractions of the neighbouring kingdoms, declared himself independent, and invading Persia with a powerful force, he defeated and slew the last of the Seljookian monarchs, and subdued the greater portion of their dominions. He extended his inroads over Syria, and had become the terror of the Ayoubite princes and the sultans of Iconium; and he finally established his wide dominions from the Persian Gulf to the borders of India and Turkestan.³

Zinghis Khan.

The continued irruptions of those barbarous tribes into the regions of civilization had given rise to scenes of calamity and of revolution hitherto unequalled in the history of the world. Conquests had no doubt been achieved before by the warlike nations of antiquity, and the rage of war had been satiated by the ruin of peaceful cities and the massacre of the people. But these evils, great as they were, fell far short of those inflicted on mankind by the conquests of the pastoral tribes, which were carried to such a height by Zinghis Khan and his destroying bands, as nearly to threaten the desolation of the earth, and the extinction of all the arts, improvements, and civil institutions of society. This Tartar chief, or savage, who was originally the khan of a horde of shepherds, comprising 30,000 or 40,000 families, inhabiting the countries to the north of China, seems, about the beginning of the 13th century, to have united under his sway all the other tribes which, under the various designations of Huns, Turks, Moguls, or Tartars, wander on the spacious high lands and plains of Asia, between China, Siberia, and the Caspian Sea. He became, to use the expressive language of the great Roman historian, "the monarch of the pastoral world, the lord of many millions of shepherds and soldiers, who felt their united strength, and were impatient to rush on the mild and wealthy climates of the south."

This great conqueror swept over the whole breadth of the earth with his barbarian hordes. Art and nature were found alike unequal to stay his destructive course. He traversed mountains and rivers, barren deserts and unhealthy climates, with resistless speed; and he oppressed the walled towns by his countless multitudes. The Chinese were the first enemies with whom, after quitting the desert, he measured his strength. His innumerable squadrons penetrated at all points the feeble rampart of the great wall. Ninety-six cities were plundered and destroyed, and the smaller towns and villages were reduced to ashes; the aged were given up to the destroying sword; a prodigious multitude of children were carried away, who were afterwards massacred in the march homeward; besides a rich spoil in gold, silver, silk, and cattle.⁴ In a second expedition he was equally successful; the emperor fled before his enemies to a more southern residence; Yenking or Peking was taken and burnt; and, through the weakness and division of the Chinese councils, the five northern provinces of the empire were reduced under the dominion of the Moguls.⁵ The invincible arms of Zinghis were now turned against the sultan of Carisme or Kharisme, who, as has been already mentioned, ruled over the fertile countries situated between the Oxus and the Jaxartes, and had extended his conquests over a great part of Persia. At this period his territories contained the flourishing and commercial cities of Samarcand, Buckharia, Carisme, Herat, Balk, &c. His troops were overpowered in a bloody conflict with the Tartar host, the country was subdued, and the rights of conquest were as usual most savagely abused. The open country was desolated; the rich cities plundered, and the inhabitants either slaughtered or carried into captivity; and in some cases every thing that had life, with the city itself, was destroyed. The cities that perished in this general ruin were, Buckharia, situated on a branch of the Jaxartes, a populous city, the centre of an extensive commerce, and the seat of science and religion; Otrar; Cojend, on the Oxus; Samarcand, situated near the source of the same river as Buckharia; Carisme, where 100,000 men were massacred, and the surviving population reduced to slavery; Balk, on the Upper Jaxartes, which contained 200 splendid mosques, and a numerous population; Nisabaur; Herat, in Khorassan; Candahar, farther east; besides numerous other smaller towns and villages. All that tract of country which extends from the Caspian Sea to the Indus, comprehending the ancient territories of Transoxiana, Carisme, and Khorassan, and which was fertile, populous, and well cultivated, was entirely ruined by this irruption of the Tartars, so that, to use the words of the Roman historian, "five centuries have not been sufficient to repair the ravages of four years." The conquests of Zinghis, before his death, extended west from the Indus to the A. D. 1227. Euxine, from the Pacific Ocean to the Volga, and from the Persian Gulf to the confines of Siberia.

The children of Zinghis, who succeeded him, completed the career of conquest which he had begun. China, divided at that time into the two dynasties or empires of the north and south, was subdued and laid waste by his grandson Cublai, with all the unrelenting cruelty of a Tartar conqueror; and he extended his influence and the terror of his arms over the circumjacent kingdoms of Corea, Ton-

¹ D'Herbelot; De Guignes, *Histoire des Huns*, tome iii. livre 14.

² De Guignes, in his learned and laborious work *Histoire des Huns*, gives a very clear narrative of the situation and boundaries of this kingdom, and of its final ruin by the invasion of Zinghis Khan. The fate of the sultan, formerly a conqueror, who, flying from the Tartar horse, took refuge in an isle in the Caspian Sea, where he requested a horse might be allowed to feed near his tent, as the companion of his solitude, and his solace in adversity, is particularly touching. See tome iii. livre 14.

quin, Cochin-China, Pegu, Bengal, and Thibet. A new dynasty of Mogul princes was established in China, under whose sway the country gradually settled; and in the succeeding generation the habits of the invaders were mollified by the influence of civilized life. Letters, commerce, and the arts of peace were revived, and the ancient system and machine of Chinese manners and policy resumed its accustomed action. One hundred and forty years after the death of Zinghis, his degenerate race were expelled by a revolt of the Chinese, and the native dynasty of princes, namely, that of Ming, was elevated to the vacant throne.

Persia was overwhelmed by the invasion of the Tartar armies under Holagou Khan, the grandson of Zinghis. The princes who ruled in the different districts of the country, under the titles of sultans, emirs, and attabeks, were successively crushed under this great conqueror, who, advancing to the Euphrates, stormed and destroyed the city of Bagdad, put the caliph to death, and thus for ever extinguished the line of the Abassides. Syria was overflowed by the torrent of invasion; Damascus and Aleppo were given up to pillage;¹ the kingdoms of Armenia and Anatolia were overthrown; and the sultans of Iconium, the last remnant of the Seljookian dynasty, were extirpated by the armies of Holagou.

The descendants of Zinghis had no sooner subverted the empire of China, than they resolved on the conquest of the western world; and collecting a mighty host, they advanced from China to Europe, inundating the intervening space with their innumerable hordes, and extirpating the reigning powers in Turkestan, Tartary, and the northern plains of Asia. They penetrated into Europe with their victorious armies, of which detachments were sent northward to contend with the Russian princes for the frozen regions of Siberia. The unity of the Mogul empire, so firmly maintained by Zinghis Khan, was weakened by the extent of its conquests. According to its original constitution, all the other khans were the dependents or vassals of the great khan, under whose investiture they held their authority. But by distance, and the various mutations of time, those ties of allegiance were gradually loosened. The different branches of the Mogul family conformed, from policy or conviction, to the religion of the conquered countries, those who ruled in China to the idolatry of the Chinese, and the invaders of the Moslem territories to the Mahometan faith; and from this diversity of religion and manners divisions arose, which terminated in a lasting disunion. From A. D. 1240 till the rise of Timour or Tamerlane, about the year 1360, the Mogul power in Western Asia was shaken by intestine strife; and a crowd of emirs, sultans, and petty rulers contended, in incessant wars, for the fragments of the broken empire; while such of the Moslem potentates as survived the invasion of Zinghis, still maintained, by their valour, the balance of power in Syria against their Tartar enemies. The Ottoman line of princes, the permanent rulers of the country, were in the mean time slowly emerging into view. Amid the anarchy which reigned in Western Asia from the downfall of independent powers, and the rise of usurpers in their place, the country swarmed with a warlike population, with loose disbanded soldiers, and adventurers of every description. Among these were many of the Turkman hordes who had formerly pitched their tents on the southern banks of the Oxus, and the khan of one of those obscure tribes was the father of the Ottoman dynasty. Othman was the first of this line who, about the year 1326, by his con-

quests, laid the foundation of the Turkish empire, which has ever since continued to rule in Syria and Asia Minor. About the year 1400 the Turks, under Bajazet, had acquired an extensive empire, the glory of which was for a time obscured by the conquests of Timour the Tartar, or Tamerlane, who began to acquire renown by his early conquests in Eastern Turkestan, or Transoxiana, about the year 1360, when he subdued the kingdom of Cashgar, and carried his conquests 480 leagues to the north-east of Samarcand.² He finally extended his dominion to the Irtisch and the Volga; and in 1398, having previously reduced the Punjaub and the province of Moul-tan, he advanced across the intervening desert to Delhi, which submitted to his arms, and was abandoned to pillage. He proceeded eastward towards the sources of the Ganges in a crusade against the idolatry of the Hindoos, who were massacred without pity; and, after an expedition of five months, he finally retraced his steps to Samarcand, without effecting any permanent conquest. In the western countries of Asia he encamped and overthrew the rising power of the Turks under Bajazet, and extended his conquests over Syria and Asia Minor, giving over its flourishing cities, such as Aleppo, Damascus, Smyrna, &c. to the sword and the flame. The rise and progress of this great Tartar chief, and his rapid successes, rivalled those of Zinghis himself; but they were not on the same vast scale, nor had they such lasting effects. The kingdoms which were conquered by Zinghis were colonized by his soldiers and inherited by his children; but Tamerlane's conquests were more like predatory inroads; and though for the time he subverted the existing order of things, and trampled in the dust the principedoms and powers of the country, yet, as the flood of his invasion receded, those powers quickly resumed their sway. In Asia Minor the Ottomans speedily regained their ascendancy on the ruins of the Greek power. They reared up, in the middle of the 15th century, the permanent fabric of their empire. Towards the end of the same century Persia was, by a singular revolution, transferred from the Tartar chiefs to the dynasty of Sef-fanean kings, or saints as they were considered before their elevation to the throne. Under their rule the country continued without any material change, until it was invaded in 1722, and conquered by Mahmood, the first of the Afghan rulers of Persia. The independence of Persia was vindicated by the rise of the celebrated usurper Nadir Shah, who, ascending the throne about the year 1730, quelled all internal dissensions, and re-established the Persian empire in its ancient greatness and glory. He restrained the Turks within the western boundary of the Euphrates; on the north he extended his dominions to the Oxus, and awed by the terror of his arms the Usbecks, and other wandering tribes of the desert; and on the east he conquered Hindostan, which he plundered of its wealth, and fixed the Indus as the boundary of his empire. Under his successors Persia has decreased in extent of territory and in power, but has not been subjected to any violent revolution, and still continues one of the independent though declining empires of the east. In 1747 the Afghans, under the new dynasty of the Doo-ranee kings, resumed their independence, which they still retain. Their kingdom is bounded on the east by the Indus, and on the west by Persia, or by intervening deserts.

In Hindostan the influence of the Mahometan con-querors, which was firmly established in 1210, was gra-

¹ "Les hommes," says De Guignes (tome iv. livre 17), "les femmes, et même les enfans à la mammelle, furent égorgés."

² Gibbon, vol. xii. chap. 65.

Asia.

dually extended over the southern provinces, amid rebellion and massacre. The uncertain dominion of the country appears to have been shared among a crowd of tributary princes, who, from their intestine quarrels, became an easy prey to the invader. Delhi was the capital of the Mahometans; and their conquests were extended over Malwah, the Deccan (by which we mean the country between the Nerbuddah and the Krisna rivers) and the Carnatic, which was ravaged from sea to sea. The invasion, or rather the predatory inroad of Timour in 1398, did not subvert the Mahometan dynasty, which terminated in 1413 by the death of the monarch. The throne was then filled by a Seid, *i. e.* one of the race of Mahomet, whose posterity enjoyed it till the year 1450, when an Afghan took possession of it, and all Hindostan was divided into separate governments. After an interval of reviving prosperity, the empire, about the year 1516, fell again into utter confusion, which paved the way for the conquest of the country by Sultan Baber, a descendant of Tamerlane and of Zinghis Khan, who being driven from the provinces situated between the Indus and Samarcand, over which he reigned, determined to try his fortune in India. He crossed the Indus in 1518, and having defeated the emperor of Delhi, he established the dynasty of Timur, or the Mogul line as it has been termed, which was illustrated by two of the greatest princes that ever reigned in India, namely, 1st, Acbar, who, from 1555, reigned 51 years, and subjected to his sway all the provinces that had revolted, from Agimere to Bengal; and, 2dly, by Aurungzebe, who, after the interval of anarchy that continued for 50 years on the death of Acbar, ascended the throne in 1660, and died in 1707, in the 90th year of his age. In this reign the dominion of the Moguls was extended over the Deccan, the whole of which, excepting only the mountainous and inaccessible parts, was either entirely subjected, or rendered tributary to the court of Delhi.¹ His authority reached from the 10th to the 35th degree of latitude, and to nearly the same extent in longitude; and his revenue amounted to 32 millions sterling. The Mogul empire gradually fell to pieces under a succession of feeble princes; and about the year 1750 it was reduced to the city of Delhi, and a small tract of adjacent territory. The last imperial army that ever appeared in the field was defeated by the Rohillas in 1749; and during this period the whole country was one scene of commotion, all the viceroys and petty feudatories of the Delhi sovereigns,—the various mountain tribes, such as the Rajpoots, who ruled in Agimere,—the Seiks, who had become formidable, and had established themselves in Lahore,—and the Jats, a tribe also in the north of India,—contending in arms for independence. Nothing remains of Mogul greatness but the name, which was, and is still, used as the symbol of sovereignty, and the sanction of all political and civil rights.

The decline of the Mogul empire paved the way for the rise of the Mahratta power, which had already become formidable in India under its founder Sevajee. At his death in 1680 he had acquired considerable dominion on the western coast of India. The confusion and anarchy that followed the death of Aurungzebe greatly facilitated the Mahratta conquests; and in 1740 this growing empire, which was divided between two chiefs, the one residing at Poonah in the west, and the other at Nagpoor in the east, occupied the whole track from the western sea to Orissa, and from Agra to the Carnatic.² The

Mahrattas, thus daily gathering strength, and the Mahometans, were now the two great rival powers in Hindostan. The contest between them was brought to an issue in the memorable battle of Paniput in 1761, when the Mahratta host of 200,000 men was entirely overthrown, with the loss of the greater part of their army, and their best generals; and from that fatal day their power began to decline.

The rise of the British power forms an important era in the history of India. The unwarlike inhabitants of British Hindostan, successively subdued by the Greek, the Mahometan, and the Tartar armies, were now destined even more surely to fall under the science and discipline of Europe. The French maintained their ground in India only for the short period of 12 years, from 1749 to 1761. The British, who engaged about the same time in the wars and politics of India, were more successful. The battle of Plassy, in 1757, fought with Surajah Dowlah, nabob of Bengal, gave them a firm footing in the country. The war which followed terminated in their favour; and in 1765 they acquired the right of collecting the revenues of Bengal, which was in fact the sovereignty of the country. The jealousies of the native powers, excited by the encroachments of the Europeans, gave rise to new contests. But victory was still the result of each new struggle; and all the wars undertaken against the British only tended to consolidate and extend their empire. The long and memorable struggle with Hyder Ali and his son Tippoo, who ruled in Mysore, terminated in their entire overthrow in 1799, and in the capture of Seringapatam, the capital of the kingdom. The peace of India, which was re-established by this decisive success, was not, however, of long duration. The British were regarded by the native princes as the common enemies of Indian independence. They were alarmed by their growing power, and they naturally united with each other against them. The British, on the other hand, viewed with equal jealousy the hostile dispositions of the native princes. They foresaw that a struggle would take place for the dominion of India, and they made suitable preparations for the impending crisis. A combination of the Mahratta chiefs Scindiah and the rajah of Berar was overthrown by the skilful and vigorous movements of Sir A. Wellesley. Holkar, who rashly measured his strength with the British, was also overthrown, and peace was re-established. In 1817, when the British were prosecuting the war against the Pindarees, the Mahratta powers formed a new coalition, and took the field in great force. They were separately overthrown: the Peshwa, the head of the Mahratta states, was deprived of his throne, and his territories placed under the administration of the British. The rajah of Nagpoor was also driven from his dominions; and Holkar was again humbled, and deprived of his rank as an independent prince. This was the last expiring effort of Indian independence, by which the struggle was closed, and the dominion of the British firmly established, from Cape Comorin to the Himalaya Mountains.

Amid those revolutions, of which we have attempted to give a brief sketch, it is not surprising that some of the most ancient empires of Asia should have entirely disappeared; that populous cities should have fallen into decay and ruin; and that extensive countries, once the seats of wealth, commerce, and science, should now lie desolate. The Babylonians and Assyrians have been long blotted out of the page of history; and no traces of them remain in the population of the world. The kingdom of

¹ Dow's *History of Hindostan*, vol. ii.; Major Rennel, *Memoir of a Map of Hindostan*, Introduction, lxi.

² Major Rennel, Introduction, lxxxv.

the Jews has also been overthrown; but this ancient race are still wanderers on the face of the earth, and are found in most parts of Asia. There are other five principal races, who, it is remarked by Sir W. Jones, have in different ages divided among themselves as a kind of inheritance, and who still occupy, the vast continent of Asia, with the many islands depending on it. These are the Hindoos, the Chinese, the Tartars, the Arabs, and the Persians. The origin of those different races is a curious subject of inquiry, and must be sought for in the remotest antiquity, and from the doubtful analogies supplied by religion, manners, and language. Sir W. Jones, who has so well illustrated many obscure points of ancient history, is of opinion that Persia was the original seat of mankind, from which, as from a common centre, they have gradually spread over the earth. According to his learned hypothesis, deduced from ancient works and an examination of the primitive languages, a flourishing empire was established in Persia or Iran, in the earliest dawn of history; and the population consisted of the three distinct races of Hindoos, Arabs, and Tartars. About the era of Mahomet, it appears that, besides the language in common use, the learned had a language of their own, which had the name of the Pahlavi; and there was the still more ancient and abstruse language of the Zend, in which some sacred books were written, only known to a sect of priests and philosophers. The Pahlavi he clearly proves to be of Chaldaic origin, and the Zend, from an imperfect vocabulary which he procured, to be a dialect of the Sanscrit, the ancient and learned tongue of the Brahmins in India. Having thus ascertained the analogy between the language of the ancient Persians and that of the Arabs and the Hindoos, he concludes that they must have originally been the same nation; and that, as Persia could not be peopled from the east by the Hindoos, whose religion forbids them to emigrate, nor by the Arabs from the west, as we have not the slightest tradition of any such emigration, both Arabs and Hindoos must have come from Persia, since we may still trace in this country the remains of their respective tongues, all of which appear to have been derived from one common and more ancient root.

The people of Thibet are descended from the Hindoos, and, according to the hypothesis of Sir W. Jones, who on all those subjects unites solid reasoning with the most profound learning, have engrafted the heresies of Buddha on their ancient religion. Their language, though it has been corrupted by an intercourse with the Chinese, still bears the traces of a Sanscrit origin. The Afghans or Patans, who occupy Afghanistan, between Persia and Hindostan, are said to have sprung originally from the Jews; and their language, which is derived from the ancient Chaldee, so far confirms this tradition. The Japanese and the Chinese are evidently derived from a common stock, their literature, religion, and manners being the same. The Burmese are considered, on the best evidence, to belong to the Hindoo race, though others give them a Tartar origin.

The Tartars, under which appellation we include the hordes of shepherds who range over the vast plains of Asia, under the names of Scythians, Huns, Mongols, and Kalmucs, differ entirely from the Hindoos and Arabs in

features, complexion, and form, as well as in manners and language, and appear evidently to be a distinct race. Their language, which is the Turci or the Turki, of which the modern Turkish is a dialect, might, according to Sir W. Jones, be easily traced to a different root from the others. This ancient Tartarian language he mentions, on grounds which it would not be easy to disprove, was current in Persia at a very early age; and hence he concludes that the Tartars formed part of the ancient population of Persia, and, along with the other two races, issued from that country to occupy the deserts of Asia. The Chinese, according to the same learned author, whose opinion is founded on the Sanscrit institutes of Menu, were originally a military tribe of the Hindoos, who, abandoning the ordinances of the Brahmin religion, and living in a state of degradation, emigrated eastward, and occupying the countries bordering on Hindostan, laid the foundation of the Chinese empire. But the whole country has been since overrun and conquered by hordes of Tartars; and from the intermixture of those two races have sprung the modern Chinese, whose coarse, broad, and Tartar-like physiognomy bears no longer the traces of their Hindoo ancestors.

We have no sure data to determine from what country the population of the world at first proceeded; and most of the theories on this subject rest chiefly on the doubtful analogies of language, or on other evidence equally uncertain. It is the opinion of many learned inquirers that the Chinese are not Hindoos; but that they, along with all the inhabitants of Eastern Asia, are originally a Tartar race. This opinion is founded on the usual evidence of a common origin, namely, a resemblance in features, language, and customs. Dr F. Buchanan, who travelled into the Burmese country, and has furnished some interesting information respecting this people, observes, that "there is one very extensive nation which inhabits the east of Asia, and that it includes the Eastern and Western Tartars of the Chinese authors, the Kalmucs, the Chinese, the Japanese, and other tribes inhabiting what is called the peninsula of India beyond the Ganges, and the islands to the south and east of this, as far at least as New Guinea." The features and figure of all those different nations which he describes indicate a Tartar origin. They are in stature short, squat, and robust; their face is sharpened towards the mouth and chin, while at the cheek-bones it is very broad. Eyebrows that scarcely project; narrow eyes, placed rather obliquely in the head; a very small nose, with the apertures of the nostril nearly circular; harsh, lank, and black hair, complete the portrait of a Tartar face. By such features they have been distinguished in all ages. The ancient writers, in describing the barbarians who invaded the Roman empire, particularly mention their small twinkling eyes, punctured as it were in their heads; their broad shoulders, short stature, and their shrill voices, which is not mentioned by Dr Buchanan as characteristic of the inhabitants of Eastern Asia.¹ There seems no reason to question those strong evidences of a Tartar origin; and admitting so far the theory of Sir W. Jones, that the Chinese were originally descended from a tribe of Hindoos, they appear in the course of ages to have lost all traces of that ancient race.

¹ Ammianus Marcellinus speaks of their firm and compactly built limbs, their thick necks, their large and bent figures; and, in a tone of exaggeration, compares them to two-legged brutes, or to the rude figures which were placed by the Romans at the end of bridges. He mentions also the practice which prevailed among them of rooting out the hairs of their beard. "Ubi quoniam ab ipsis nascendi primitis infantum ferro sulcantur altius genæ, ut pilorum vigor tempestivus emergens corrugatis cicatricibus hebetetur, senescunt imberbes absque ulla venustate, spadonibus similes; compactis omnes firmisque membris, et opimis cervicibus; prodigiosæ formæ et pandi, ut bipedes existimes bestias, vel quales in commarginandis pontibus effligiati stipites dolantur incompte. (*Amm. Marcell. lib. xxxi. cap. ii.*)

Asia.

The tribes who inhabit the great Asiatic archipelago, which extends from Madagascar to the Philippines and the neighbouring peninsula of Malacca, bear in their features, language, and customs the undoubted marks of the same origin; and as the Sanscrit may be traced as the root of all the various dialects spoken in these islands, they appear to be descended from the Hindoos. But in the lapse of ages, and in the various chances of war or migration, different nations may be intermingled; the original traits by which each was distinguished will then gradually disappear, so that it may not be possible to discern the traces of a common origin in the varieties of the same race. Like the Chinese, therefore, the inhabitants of the great Arabic archipelago may have come originally from Hindostan, bringing with them the Sanscrit tongue; and in the course of migration or conquest they may have acquired the features of the Tartars, without losing their native language. Sir Stamford Raffles, not less distinguished by his eminence in eastern literature and antiquities than as a legislator and a statesman, is of opinion that the Asiatic islands were peopled from that portion of the continent which lies between Siam and China. "The less civilized of the tribes," he observes, "inhabiting the islands, approach so nearly in physical appearance to that portion of the inhabitants of the peninsula which has felt least of the Chinese influence on the one side, and of the Burman and Siamese on the other, and exhibit so striking an affinity in their usages and customs, as to warrant the hypothesis, that the tide of population originally flowed toward the islands from that quarter of the continent lying between Siam and China. But at what era this migration commenced—whether, in the first instance, it was purely accidental, and subsequently gradual, or whether originally it was undertaken from design, and accelerated at any particular periods by political convulsions on the continent, we cannot at present determine, as we have no data on which to rely with confidence. It is probable, however, that these islands were peopled at a very remote period, and long before the Burman and Siamese nations rose into notice."¹ Mr J. Crauford, who resided for nine years in the Asiatic islands, and whose history of those countries displays extensive research, and a profound knowledge of eastern literature and antiquities, adopts a different hypothesis respecting the original population of the Indian archipelago. He describes the original inhabitants to consist of two races, one a brown-complexioned people, with lank hair, and in their persons short, squat, and robust, supposed by other writers to be Tartars; and the other, a negro race, of a puny stature and feeble frame, in complexion black, or rather sooty-coloured, with woolly or frizzled hair. The brown-coloured race compose the civilized portion of the people; and they have supplanted the negroes, who are constantly found in a savage state in Sumatra, Java, and Celebes, where civilization has made the greatest progress; while in New Guinea and other islands the negroes are almost the sole inhabitants. The origin of these two races, and the period when they settled in the Asiatic islands, is, according to Mr Crauford, buried in the remotest antiquity. The Tartar origin of the one race, though supported by many writers of learning, and the African origin of the negroes, is treated by him as absurd and unfounded. "Either hypothesis," he observes, "is too absurd to bear the slightest touch of examination. Not to say that each race is radically distinct from the stock from which it is imagined to have proceeded; the physical state of the globe, the na-

ture of man, and all that we know of his history, must be overturned to render these violent suppositions possible." Dr F. Buchanan, Sir Stamford Raffles, and others, deduced the Tartar origin of those insular tribes from their form and features, which is the best evidence we can have where history is silent. The prevalence of the Sanscrit language in these islands has also, and with apparently some reason, been supposed to indicate the quarter from which the tide of population flowed; nor is it easy to see how the migration of a people from the continent of Asia into this archipelago is at variance with the "physical state of the globe, the nature of man, and all that we know of his history." Mr Crauford traces the various languages of the Asiatic islands to one common root. From this fact he concludes those islanders to have all sprung from one source, and he fixes on Java as their original place of settlement. Here he supposes they took up their abode when they were little better than wandering savages; whence they gradually spread over the other islands. Now it is on the same ground that others trace their origin to some continental nation of great antiquity. The language of a nation may throw light on its origin and its subsequent migrations; and in the present case it is admitted by Mr Crauford that there is a large infusion of Sanscrit in all the Polynesian tongues; that it is "a more essential, necessary, and copious portion of the insular languages than Arabic;" that it exists in "a state of as great purity as the articulation and alphabets of the archipelago would admit, nearly unmixed with any modern dialect of which it is a part, and apparently in a state of original purity;" and that it is "pure and abundant as each dialect of the same tongue is improved, and rare and corrupt as the language is common and popular." Sanscrit words, according to those who are versed in both languages, abound in the court dialect of Java in the proportion of three to four, and seem to constitute its basis; in the Kami, or learned language of the priests, they occur still more frequently, and in their original purity; they are also common in the written language, and are found, though not so generally, in the ordinary dialect of the people. The existence of Sanscrit to such an extent in the languages of Java and the other islands, does not, according to Mr Crauford, prove that these islands were peopled by emigrants from Hindostan. He acknowledges that the fact of the Sanscrit not being mixed in their languages with any living dialect of India, is somewhat puzzling, and not easily reconciled to his theory; but on farther consideration, he thinks this fact tends rather to explain the manner in which it was introduced, which he ascribes to a few Hindoo missionaries or priests brought to those islands from a desire to propagate their religion. They would naturally, he supposes, use the Sanscrit in teaching the mysteries of their faith, which, being mixed with the common language of the country, would form the Kami or learned language of the priests, and would thence be diffused in a corrupted state over the common dialect of the people. From the prevalence of Sanscrit to such an extent in the Polynesian dialects, as well as from the ancient monuments of Hindoo idolatry which are found everywhere in those islands, it seems highly probable that they must, at a very early period, have been the seat of a Hindoo empire, which has disappeared in the lapse of ages, while the Hindoo superstition has been supplanted by the Mahometan creed. Whether this empire was established by conquest in that early period, while the Sanscrit was yet a living language, or whether the Hin-

Asia.

² *History of the Indian Archipelago*, by John Crauford, F. R. S., vol. ii. chap. v.

doos were the original settlers in these islands, and afterwards, from the intermixture of other races, lost the traces of their ancient lineage, are points which lie hid in the darkness of antiquity. It does not seem very credible, however, that a small number of Hindoo missionaries should have had influence, as Mr Crauford supposes, to change the language of the people, and to substitute for the ancient religion of the country their own foreign superstitions. So great a change seems more probably to have been produced by foreign conquest, or by a large emigration of the Hindoo people.

Of the various races which people those islands, the Malays appear to deserve particular notice. Sir W. Jones supposes them to be descended, since the time of Mahomet, from the Arabian traders and mariners who frequented the Asiatic archipelago. But by later and more accurate inquiries they are now ascertained to have been originally settled in Menangkabau, in the centre of the island of Sumatra, and to have ruled over the whole country, from which they sent out colonies to the other islands. The Malayan annals examined by Mr Marsden,¹ and other documents, satisfactorily prove that, so far from emigrating, as was generally supposed, from the peninsula of Malacca to the Asiatic islands, they were original settlers in Sumatra, from which they issued to invade and conquer the Malacca peninsula; and they had established a powerful empire prior to the Mahometan conquests. The Malays profess the Moslem creed, which was introduced about the end of the thirteenth century, and has made rapid progress among all those islanders. But their original religion was that of Brahma, blended with the antecedent rude idolatry of the country, such as is still seen among the Battas. The Malay adventurers who invaded the Malacca peninsula in the 12th century conquered the country; and the indigenous inhabitants, so far from being the stock from which the Malays have sprung, are an entirely different race, resembling more nearly the negroes of Africa. The Malayan empire, which extended all over Sumatra, is now dismembered, though its colonies have been found on the coasts of the Malacca peninsula, and throughout the islands as far east as the Moluccas.² The Malayan language is spoken without any mixture in the inland country of Sumatra; it is understood everywhere, and has extended over all the eastern islands. The Bugis in the island of Celebes are a well-known race in the eastern archipelago. During the flourishing era of the Malayan empire in Sumatra they had established that of Guah or Mengkasar in Celebes on the east: like the Malays, they sent forth numerous colonies; and at one period extended their conquests as far west as Acheen in Sumatra and Keddan in the Malayan peninsula; and in almost every part of the archipelago Malayan and Bugis settlers are to be found. In all those Asiatic islands there is, however, an indigenous race, who were settled there prior to the Malays or the Bugis; and these last appear to have been intruders, but at what period of the world cannot now be known. The native inhabitants of Sumatra, Java, and the other islands, differ from them in character, habits, and features. The Battas, in the interior of Sumatra, are a distinct people, with their own peculiar habits and language: they have been reproached by travellers for eating human flesh, of which Sir Stam-

ford Raffles produces undeniable evidence. The natives of Java are a quiet, contented race, attached to the soil, and have not the roving, maritime, and piratical habits of the Malays.

With regard to the number of inhabitants in Asia, we have no data for any accurate estimate. The Asiatics possess no statistical knowledge; and, excepting surveys instituted by government for the purposes of taxation, no other political inquiries are ever set on foot by authority. The various accounts of the Chinese population differ to the extent of 100,000,000. Those regarding Persia, Hindostan, the Asiatic islands, &c. are little more to be depended on; and still less can we expect any accurate census of the roving population of Arabia or Tartary.

The character of the Asiatics is represented in a very unfavourable light by all travellers. Lieutenant Pottinger, who travelled in Hindostan, Persia, and other countries, asserts that moral turpitude may be said to pervade the population and society of every nation in Asia of which we have the slightest knowledge:³ and this description is confirmed by other travellers, who describe the people to be dissolute in their morals, of cold and selfish dispositions, and withal cruel and treacherous; without any regard to truth, and indulging, without either restraint or shame, in the most scandalous crimes. Of all the nations in Asia the Persians are reckoned to be the most refined; and yet, according to Herbert, Chardin, and others, and more recently Fraser, Pottinger, and Sir J. Malcolm, they are stained with all the Asiatic vices of cruelty, meanness, lying, and the grossest licentiousness.⁴ The Hindoos do not rank higher than the Persians in the scale of morality; and among the Burmese and other eastern states the treatment of women, who are held to be an inferior class, and are sold into slavery by their husbands and parents, and the cruelties which they commit in war, besides other revolting customs, indicate a state of manners which, contrasted with those of Europe, may be justly considered barbarous.⁵ Of the low state of morals among the Chinese we need seek no other evidence than the inhuman practice, which is known to prevail in all the populous cities, of exposing new-born children to perish on the streets. There is no truer mark of barbarism than an indifference to the sufferings of our fellow-creatures; as on the other hand it is only in a highly civilized community that man is trained to the exercise of social benevolence. The savage is always found to be cold, unsocial, and selfish: in the progress of society this selfish principle is corrected; man is impressed with the duties which he owes to his fellow-men, and is taught to know experimentally, that it is not in the selfish pursuit of his own good, but in the mutual interchange of benefits, that the greatest sum of individual happiness is to be found. If we examine the manners, institutions, and policy of different nations, it will be seen that mankind are humane and moral exactly as they are instructed; and that as the diffusion of knowledge leads to the practice of all the social virtues, ignorance as surely produces cruelty, selfishness, and vice. Thus, among the Persians and Turks cruelties are committed which would be repudiated by the more advanced civilization of Russia; and in illustration of the same principle we may here mention a circumstance which serves to place in an equally striking contrast the manners of the English and the Chinese. An

³ See *Travels in Belochistan and Sindh*. "I hope," he adds in a note, "I shall not be stamped as a misanthrope on account of the sentiments I entertain of all Asiatics. I am convinced the farther our researches spread, and the more intimately we become acquainted with the East, we shall discover stronger, clearer proofs of the general application of the conclusion I have drawn. I should be happy to have any evidence to the contrary, but do not anticipate it."

Asia.

English vessel happened to be at anchor in the roads of Canton, when a Chinese boat was overset, and the crew precipitated into the water. The accident was observed by numbers of the Chinese, who beheld with the utmost indifference their countrymen struggling for their lives. But the officers and seamen of the English vessel instantly lowered their boats, and were seen, with all their usual zeal in the cause of humanity, striving to save the lives of those who were entire strangers to them. Now we cannot have a surer index to the station which each nation holds respectively in the scale of civilization, than the opposite conduct which they severally pursued in this case; and this insensibility to human distress is not peculiar to the Chinese; it seems to pervade the whole population of Asia; while in Europe we see everywhere proofs of active benevolence,—the most munificent establishments for the relief of misery; hospitals for the sick and infirm; houses of refuge for the aged, the blind, the destitute, and the insane; besides charitable associations of every description. For all the afflictions to which frail humanity is subject, the active sympathy of Europe supplies a remedy; and the spacious structures which, under the influence of this feeling, have been reared up in all the European towns, are at once the splendid monuments of humanity and of high civilization. In Asia the rich and the powerful associate, not to relieve, but to oppress the poor; and throughout its wide extent no asylum for distress, nor any charitable institutions, are to be seen. The miserable are left to their fate, which is generally to die unpitied, either of famine or disease. There is no part of Asia in which intelligence is widely diffused among the people; and hence, while they are to “vice industrious,” they are to “nobler ends timorous and slothful.” Yet in the exterior pomp and show of the Asiatics there is something specious and imposing; and the rich magnificence of their flowing robes, their gorgeous palaces, their splendid mosques and gilded temples, are calculated to raise ideas of high improvement, which a nearer inspection fails to realise; and, after all, what is there in this tinsel glare of oriental luxury that can be compared to the severe simplicity and solid refinements of Europe.

This degraded state of society seems to be the joint effect of tyranny and superstition. In Asia there is no government which wears even the semblance of freedom. In form, as well as in practice, they are purely despotic, the princes being tyrants, and the people slaves. Nor is the power of the prince controlled by the influence of manners, as in Europe, where the monarch, however absolute, seldom indulges in the licence of despotic sway, and where life and property are fully protected. The manners of Asia favour the exercise of unlimited power; and this vast continent is accordingly one scene of excess and misrule, where the mere will of the monarch is a warrant for the proscription and death of any individual, however powerful, and for the ruin of his family. The people, ruled according to those severe maxims of despotism, live in continual dread of violence and wrong; and they naturally resort, in self-defence, to fraud, falsehood, and treachery, which are the resources of weakness. Thus all sense of independence is at last extinguished; and under the iron rod of their political masters they degenerate into abject slaves, without honour, intelligence, or morality. Despotism in Asia assumes so severe a character, that it invades the security of private life, relaxes all social ties, and re-acting on the people with its pernicious influence, tends still farther to debase them, and to fit them for the endurance of its degrading yoke.

The prevailing superstitions of Asia have had their due share in corrupting the manners of the people. In Asiatic Turkey, in Arabia, Persia, and partly also in Hindostan and

the Asiatic isles, the people have adopted the Mahometan faith; in Hindostan they have followed the religion of Brahma; and in Thibet, and farther eastward among the Burmese, in China, and the isles of Japan, the religion of Buddha or Foe is universally established, which, however corrupted in its various forms and idolatries, is still known to be derived from the Brahminical faith. Now all those different systems enjoin a variety of minute observances, and tedious pilgrimages and penances, a strict compliance with which constitutes the essence of religion. A pilgrimage to Mecca, for example, atones for all the iniquities of a Mahometan life; and the Hindoos and others have their pilgrimages and penances for the expiation of guilt. A relaxation of morals is the consequence; and hence in those eastern countries a strict profession of religion is not inconsistent with the most scandalous crimes.

The sanction given to polygamy by all the systems of religion in the East has also tended to encourage licentiousness. Mahomet found it convenient to allow this indulgence to his followers; and the Hindoos, the Burmese, the Chinese, and most of the other Asiatic nations, follow the same rule. In all Christian countries marriage is respected as a sacred and an honourable tie, equally binding on both parties; and experience proves, that where its obligations are duly fulfilled, it is calculated to produce all the happiness and virtue which can be attained by man in this sublunary state. In the intercourse of a European family the best affections of our nature are called forth. Here, as the poet expresses it,

Flows the smooth current of domestic joy;

and in those scenes the rising generation receive, from the example and tuition of parents, those just and early impressions, which are never erased. How different are the baneful consequences of polygamy, which, being contrary to the order of nature, must be upheld by tyranny, and which degrades the weaker sex, from being the free and equal companions of man, into the slaves of his pleasures. The domestic tyrants of the East rule with absolute power over all the inmates of the harem; any of whom, in a fit of rage or jealousy, they may consign to a cruel death, no eye witnessing the deed. The effect of polygamy in this manner is not merely to taint the morals of society, but the laws and policy of the state. It establishes a tyrant, not on the throne, which would be the lesser evil, but at the head of every family; and on his unruly passions the law imposes no restraint. Hence in Asia domestic comfort, so much prized in Europe, cannot be known. An Asiatic family is not the abode of purity and of domestic peace, but of licentiousness and strife; the husband and father the object of terror rather than affection; the women his abject slaves, leading a life of jealousy and malice, and often conspiring against each other by the most diabolical arts. The institution of polygamy, which in this manner converts one half of the community into tyrants and the other half into slaves, has proved, in every country in which it has been introduced, the bane of morality as well as of social peace. In Europe the purer influence of Christianity, consecrating the marriage union, and impressing on man a just consideration for the other sex, has raised them to the rank in society which properly belongs to them. It has released them for ever from the bondage of tyranny and vice; and under its mild and beneficent maxims the nations of Europe have attained to a degree of morality, refinement, and intelligence, which distinguishes them to their advantage above the most polished nations of antiquity, and presents a decided contrast to the licentiousness and misery of the East.

But if such be the state of society among the civilized inhabitants of Asia, what, it may be asked, is the condition of the

Asia.

Mann of the

of its rude tribes? Among those semi-barbarians who have no fixed habitations, but who dwell in tents, migrating periodically with their flocks in quest of pasture, all crimes of violence, such as rapine, revenge, and murder, prevail without any restraint. The pastoral tribes of Asia retain all their Tartar habits of ferocity; robbery is their daily occupation, handed down from father to son; and they are perpetually engaged in predatory inroads, in which they carry off as their lawful prey all that they can seize—corn, cattle, goods, and men and women, who are sold for slaves. If any traveller were to venture within this region of violence, he would be robbed and murdered without mercy; and no merchandise can be transported from one place to another without a sufficient escort. The regular commerce of Asia is in consequence carried on in caravans, or large companies of merchants, who travel together for safety; and even these are not secure from the savage tribes, the remnants of the Tartar population, who inhabit the mountains and central plains, and who frequently emerge from their fastnesses in great force for the purposes of plunder. Such were the shepherds who, under Zenghis Khan and Tamerlane, issued forth in innumerable bands, subverting the great empires of the world, and extending their dominion from sea to sea. But various causes have concurred to circumscribe their power. Among these we may reckon the invention of fire-arms, which in war gives the entire ascendancy to civilized nations. Prior to this invention the weapons used were extremely simple, and could be easily fashioned by the rudest tribes. In archery, or in the use of the sling, the merest savages may excel; and for a close encounter the spear or the sword could be easily procured, and as effectually wielded by a barbarian as by any other arm. But the *matériel* of modern war is far more complicated and expensive, and cannot be procured without the aid of wealth, and the nicest mechanical art as well as science; so that it is justly observed by the historian of Rome, that in the present state of the military art, a nation must be civilized before it can conquer other nations. Since the invention of fire-arms the superiority of civilized over barbarous nations has been seen in every encounter which has taken place, and “the reign of independent barbarism has been contracted within a narrow span.”

The extensive region of Tartary, which occupies the centre of Asia, has never been very distinctly defined; but it is surrounded on all sides by the civilized empires of Asia,—on the north by Asiatic Russia, and on the south by Persia, Hindostan, and China; and as the use of fire-arms has augmented the military strength of these different states, they have gradually extended their sway over the savage tribes on their frontiers. Russia, which was overrun by Tamerlane and other conquerors about the end of the 14th century, was, after about 200 years of obstinate and bloody wars, emancipated from the Tartar yoke; and it has ever since been making reprisals on its barbarous enemies, having reduced the tribes on its frontiers—the Kalmucs, the Bashkirs, the Kirghiscs, who inhabit the banks of the Volga and the country on the shores of the Caspian Sea, besides numerous other Tartar tribes on the Chinese frontier, near the sources of the Irtisch, the Obi, the Yencsei, and the Lena. Her wars with the Turks also, an Asiatic tribe, though of a different origin from the broad-featured race of Tartars, exemplify in a striking manner the warlike superiority of civilized nations. The contests of China with the barbarous hordes of Mongols, Kalkas, and Eluths, to the west and north-west of her territory, and with the Mantchoo Tartars, who inhabit the country to the north, bordering on the Pacific Ocean, have also terminated in their entire subjection. They have been successively subdued by the Chinese armies; and the missionary Gerbil-

lon, giving an account of a great victory gained by the Chinese, ascribes it to the superiority of their artillery, which the barbarians had no means of opposing. Persia has been long a feeble power; and the Tartar tribes who range along her northern and eastern frontiers are still extremely powerful, and frequently molest the adjoining countries by their incursions. Independent Tartary may now therefore be comprised within the following boundaries, namely, the Altai Mountains on the north, which form the southern boundary of the Russian empire; the Caspian Sea on the west; Chinese Tartary on the east; and Persia and Hindostan on the south. These boundaries inclose a space of about 1200 miles in length, from the Altai Mountains to Persia; and 900 in breadth, from the Caspian Sea to Chinese Tartary. To this must be added the country between Hindostan and Persia, including Sindh at the mouth of the Indus; and westward the mountainous regions of Belochistan, as well as Afghanistan. In the high district of Balk, which is within this space, and which is situated on the northern declivity of the Hindoo Coosh or Himalaya Mountains, and in Buckharia or Bokhara, on the fertile banks of the Oxus and the Jaxartes, where are the towns of Buckharia, Samarcand, Khyvah, Koukan, Khojund, and Murghelan, &c. some form of civil order is maintained by the independent princes of the country; but with these exceptions the Tartar manners still prevail throughout this extensive region. The towns are thinly scattered, and the pastoral hordes range over the face of the land in all the licence of savage freedom. These consist, not of the Tartars who possessed the country in the time of Tamerlane, but of the Usbecks, a Turkoman tribe, who appear to have descended, with the whole mass of their people, from the inhospitable countries in the north, to the fine plains of the Oxus and the Jaxartes, and to have expelled the Tartars, whose place they now occupy. The Turkoman tribes, who inhabit the Elburz Mountains to the south of the Caspian, and the deserts of Kharasm, which extend eastward from this interior sea about 600 miles, are described by Fraser, in his instructive work on Persia, as singularly fierce, cruel, and blood-thirsty in their habits. They pour down from their deserts in great force on the cultivated districts, plundering villages and caravans with every circumstance of atrocious outrage, murdering on the spot the old, the feeble, and the helpless, and carrying into slavery those who are fit for labour, and thus depopulating extensive tracts that were before fertile and well inhabited. On the east of Persia the same ravages are committed by other tribes, who dispose of their captives to slave merchants, by whom they are carried to the markets of Buckharia and Khyvah. On the south the wild inhabitants of Belochistan, so well described by Lieutenant Pottinger, one of the most judicious and enterprising travellers of modern times, plunder and murder their prisoners, or carry them for sale to some of the great slave-markets in the East. Numerous tribes of shepherds feed their flocks on the banks of the Oxus and the Jaxartes; and they are found scattered over all the northern and eastern countries of Central Asia, as far as the boundaries of Russia and China. But in the present improved state of the military art they are no longer formidable, and they waste their force in casual inroads, which are easily repelled.

From the earliest ages the countries of Western Asia, Progress namely, Asia Minor, the valley of the Euphrates and of disco-Tigris, and Persia, were familiarly known to Europeans; very in Asia. but of the northern plains inhabited by the Scythian tribes, and of the rich and improved countries of Hindostan and China in the east, they were only informed by vague and inaccurate reports, which were slowly corrected by the progress of commerce or of conquest. Of the ancient

Asia.

expedition of Semiramis into India we know nothing more than that her armies were forced to retreat with loss. But the subsequent invasion and conquests of Darius extended the knowledge of the Europeans to the modern provinces of Lahore and Moulton, commonly called the Punjab, or the country watered by the five head branches of the Indus. Herodotus describes the climate of the country as intensely hot; the inhabitants in some points as little better than barbarians; and with a small grain of truth he mixes the strangest and most absurd fables. He mentions the populousness and wealth of the country, and the staple produce of cotton growing wild on trees; also the story of the white ants turning up the earth and digging up gold, which has been copied by succeeding writers; and, finally, the region of the five rivers as bounded by a barren plain, which must no doubt be the sandy desert that lies between the valley of the Indus and the Ganges. The Scythians or Tartars who wandered over the northern and eastern plains of Asia were only known by their irruptions into Europe. The two tribes of the Massagetæ and the Sacæ, the former inhabiting the desert plains to the east of the Aral and north of the Jaxartes, and the latter the country to the north-west of India, are mentioned by Herodotus and other ancient writers; and their description is merely a detail of pastoral manners. The expedition of Alexander into India was a great step in the progress of Asiatic geography. This warlike prince was intent not merely on conquest, but on the diffusion of arts, commerce, and science; and, like some modern conquerors, his army was accompanied by a body of men of science, who were instructed to measure each day the distance traversed, to make an accurate table of the various routes, and to observe and describe the countries through which they passed. Science thus followed in the train of arms; and it was by a European army that the remote regions of the East were first explored. Alexander pursuing his victorious march through Asia Minor, passed the limits of European discovery, and entered the eastern country of Bactriana in pursuit of the Persian army. Having passed the Paropamisian range of the Himalaya Mountains, crossed the Oxus, and taken Maracanda, the modern Samarcand, he advanced northward to the Jaxartes, where he pursued the Scythian host into the northern deserts to the eastward of the Aral. Retracing his steps, he again crossed the Paropamisian Mountains, and advancing eastward among hostile tribes, through the modern country of Cabul or Afghanistan, to the south of the Hindoo Coosh range, he crossed the Indus near the mountains, and having defeated the Indian army of Porus, he obtained the command of the country watered by the five tributary streams of the Indus, where his course was arrested by the murmurs of his troops, who refused to follow him across the desert to the Ganges. Still intent on discovery as well as on conquest, he fitted out a large fleet, and sailing down the Indus to its mouth, in the Indian Ocean, he instructed his admiral, Nearchus, to return to Persia by sea, while he took his course through the modern country of Mekran, and was nearly lost with his whole army in its sandy deserts. Nearchus directed his course along the shores of Asia, and triumphing over the perils of unknown seas, arrived safely in the Persian Gulf, which he ascended to the mouth of the Tigris. This is the first great voyage of discovery of which we have any authentic account; and considering the age of the world in which it was accomplished, it must be viewed as a singular display of courage and of nautical skill. Alexander was not equally successful in tracing the connection of the Red Sea with the Indian Ocean, which remained unknown until the reign of the Ptolemies in Egypt.

Seleucus, the successor of Alexander, carried his arms

into India for the purpose of completing its conquest; but he does not appear to have reached the valley of the Ganges. He sent, however, to the court of Sandracottus, an Indian prince who reigned over all the countries from Delhi to the mouth of the Ganges, his ambassador Megasthenes, who acquired the most important and clear information respecting those unknown regions. He visited the celebrated city of Palibothra, the site of which has so much perplexed modern geographers; and, with some admixture of fable, he accurately describes the countries on the Ganges, and their productions; the amazing size of the rivers; the most remarkable animals which he saw, among others the Bengal tiger; and the manners of the people, and their division into castes, with other singular customs.

During the reign of the Ptolemies in Egypt the geography of Asia was still farther illustrated, not by conquest, but by commerce. Alexandria was at that time the great emporium of the eastern trade; and India was explored in its most remote parts, for the precious commodities which it was supposed to produce. The Egyptian mariners entering the Indian Ocean from the Red Sea, and coasting along the Arabian shore, stretched across the Persian Gulf by the help of the south-west monsoon, to the mouth of the Indus, whence they sailed southward along the Malabar coast, and doubling Cape Comorin, extended their voyage on the coast of Coromandel as far as the modern city of Masulipatam.

In the age of Ptolemy the geographer, which was a century later, the knowledge of the Europeans had extended eastward beyond the Ganges to the Burman empire and the Gulf of Siam, though it does not appear that the navigators of antiquity ever reached the Chinese coast. The commerce of India was carried on by land as well as by sea; and regular caravans commenced their route from Byzantium eastward through Asia Minor and Persia, passing through the modern cities of Hamadan and Herat; and journeying northward, and crossing the Oxus and the modern country of Buckharia, they passed the great branch of the Himalaya Mountains which runs northward from the main range under the modern appellation of Beloor Taugh; and descending into the lower plains of Little Thibet, they assembled in great numbers, and, after halting for some time, took their journey to the capital of Serica or China, which occupied a period of seven months. The description given of the Seres as a frugal and mercantile people, averse to all intercourse with strangers, and carrying on their trade at a single station on the frontier, answers entirely to the modern character of the Chinese. The commerce, which during the flourishing era of Rome was carried on between Europe and the eastern parts of Asia, was interrupted by the inroads of the barbarous nations who assailed, and in the end overthrew, the Roman empire; and all knowledge of Asia was for a time lost. It was not till the 6th or 7th century, during the reign of the caliphs at Bagdad, that the Arabian geographers acquired a knowledge of those countries. During this period the country to the west of the Beloor Taugh Mountains, which stretch northward nearly to the frontier of Siberia, consisting of extensive plains, watered by the Oxus and the Jaxartes, was well known to them; and they were imperfectly acquainted with the southern plains of Asia inhabited by the Tartars, though they were as usual the subject of fables. The eastern countries of Hindostan, the beautiful region of Cashmere, the great Asiatic plains, and China, with the island of Sumatra and others, were known to the Arabian geographers, though they seem to have had no correct knowledge of the Asiatic shores. Their accurate description of Chinese manners leaves no doubt of their having reach-

Asia.

ed that country. The invasion of the Holy Land by the crusaders tended, among its other consequences, to introduce into Europe a knowledge of those countries in Asia which were famed for wealth and the remains of ancient refinement; and from the camps of the crusading kings, as well as from the pope, some remarkable embassies were sent to the Tartar sovereigns, the descendants of the conqueror Zinghis, the site of whose capital of Karakorum is now the subject of dispute, though it is generally agreed that it must have been situated far east, in the wilds of Tartary. The object of the embassies dispatched by the pope to the Tartar camp was to divert the storm of barbarian invasion from Europe. The ambassadors were friars, who were carried to the head-quarters of the Tartars, in the eastern wilds of Asia, through countries which had never been explored by any European. Rubruquis, a friar, who was sent ambassador by St Louis to the Tartars, has given a lively and circumstantial account of his adventures. He reached the Tartar capital of Karakorum after a fatiguing and dangerous journey of more than two months, having traversed a vast tract of unknown country, and brought to the knowledge of the Europeans the immense plains and high lands of Central Asia, Eastern Tartary or the country of the Mongols, Thibet, and Cathay or China, and the eastern shores of the continent. All those countries were afterwards visited by the celebrated Venetian traveller Marco Polo, who, being dazzled by the splendid accounts diffused through Europe of the wealth and luxury of Asia, was inflamed with the desire of exploring those distant countries. He accordingly proceeded through Asia Minor, Persia, the high country of Balk, visited the cities of Cashgar and Yarkund, and skirting the great desert of Shamo or Cobi, he reached the Tartar capital of Karakorum, and finally entered the Chinese empire, of which his account is circumstantial and correct, and of which some of the magnificent cities, though they have fallen from their ancient importance, are still recognised in his accurate description. He returned to Venice by sea after an absence of twenty-four years, having obtained accounts of the eastern islands of Java, Sumatra, Ceylon, and of Ormus in the Persian Gulf, at that time the great and splendid emporium of the Indian trade. The discovery, in 1498, of the passage to India by the Cape of Good Hope, opened the Indian seas to the European fleets; and shortly after this great event, the southern, and partly also the eastern shores of Asia, were completely explored, as well as that great archipelago which extends from the Malacca peninsula to New Holland. In the interior of the continent the progress of discovery was much slower, and only kept pace with the gradual extension of the Russian dominion over the barbarous tribes in Northern Asia. The Tartars under Tamerlane in 1382 had invaded the east of Europe, had taken Moscow, and overrun all the countries on the Volga and the Dnieper. The rise of the northern empire was for more than two centuries obstructed by the inroads of the barbarians; and it was only after long and obstinate struggles that they yielded to the superiority of the Russian arms. About the middle of the 16th century Russia had extended her conquests to the Obi, and her empire was enlarged northward and eastward, until it reached the frontiers of China and the Pacific Ocean. The general form of the continent, which was exhibited in the maps from mere conjecture, was in this manner laid open to Euro-

peans; and in the course of the last century the eastern and northern shores were surveyed; also Kamtschatka, the Kurile Islands, and Jesso. The islands of Japan had been previously discovered by navigators. The relative limits of the Asiatic and American continents were traced by Behring, Tschirikoff, and other navigators, who also discovered the Aleutian or Fox Islands; and finally by Captain Cook, who advancing into Behring's Straits as far as the parallel of 70° 44', ascertained the near approach and true bearing of the two continents.

The interior countries of Asia near the Caspian and Aral Seas have been visited by Russian travellers, who have corrected some errors of long standing in Asiatic geography. Lake Aral was either unknown to the ancients, or they confounded it with the Caspian Sea, of which they supposed it to form a part, and to be the receptacle of the great river Oxus. After the fact of two separate seas was fully known, the Oxus was still supposed to terminate in Lake Aral; and its course was laid down accordingly in all the most approved charts. The Russians having visited those countries, ascertained by actual observation that the Oxus, as well as the Jaxartes, terminates in the Caspian Sea.

Eastern Asia, namely, the Chinese empire, with the source and termination of all its great rivers; the northern country of the Tartars; the course of the great river Amour; with the high lands of Central Asia, namely, Mongolia, the original seat of the Mongols, were in the course of the 16th and 17th centuries explored by the Romish missionaries, as well as by mercantile travellers. In 1624 Antonio d'Andrada, a jesuit, travelled from the coast of the Great Mogul to China. He passed through the country of Serinagur, and ascending the great Himalaya range, he and his companions endured such incredible hardships that he was forced to return. He afterwards crossed these mountains along with a caravan, and was among the earliest travellers who reached the country of Thibet, which he describes, and also the manners and religion of the people. In 1603 the missionary Goez set out from Lahore, where he resided at the Mogul court on his way to China. He travelled westward, and crossing the Indus, passed through the countries of Cabul or Afghanistan, Cashgar to the north, and the country on the banks of the Oxus; and crossing a ridge of the Himalaya Mountains, he arrived at Yarkund. From this place he journeyed with a caravan across the central country of Mongolia to China. These missionaries were received into high favour by the Chinese emperors, who valued them on account of their science, and gave them access to the public archives, which contained all the Chinese surveys of the empire and of the adjacent countries. By the help of these they exhibited with accuracy the interior geography of Thibet, and also of that extensive country beyond the Ganges which now forms the Burman empire, and which is watered by the great rivers that take their rise in the central mountains and run southward,—the Irrawaddy into the Indian Ocean, the Setang into the Gulf of Martaban, of which it forms the estuary, the Saluen into the same gulf, the Menam into the Gulf of Siam, and the Menam-Kong or the Mekong into the Chinese Sea.¹ These missionaries prosecuted with equal activity and zeal their inquiries into the interior geography of China;² they traced the great rivers the Hoangho or Yellow River, and the Yank-tse-Kiang or Blue River, to their termination as well as to their source, which they found to be in the depths of the central moun-

¹ See Crauford's *Journal of an Embassy to the Courts of Siam and Cochinchina*. Geographers are not agreed on the respective appellations of these rivers: in this we have been guided by Mr Crauford.

² For a more detailed account of these missionary travels the reader is referred to Hakluyt's *Collection of Voyages*; Purchas' *Pilgrims*; *Histoire Générale des Voyages*, Paris, 1749; and to the *Historical Account of Discoveries and Travels in Asia*, by H. Murray, who has given an equally learned, judicious, and comprehensive abstract of all the existing information on the subject of Asiatic geography.

Asia.

tains, and not in the imaginary lake of Cayamay, as had been generally believed. Grueber, who set out on his travels to the East in 1656, traversed the whole country of China, partly by land and partly by water; and his route to Europe was through the Tartar deserts to Lassa, a town in Thibet, and thence through the mountainous country of Nepaul to Battana on the Ganges, Benares, and finally to Agra, which he reached after a journey of more than twelve months. Other journeys equally enterprising were also undertaken by the missionaries. Desideri set out in 1714 from Delhi, and travelled across the Himalaya Mountains through Cashmere into Thibet; and, at a later period, Horace de la Penna, with a body of twelve missionaries, resided in the same country for a number of years. The missionary Gerbillon, who was in great favour at the Chinese court, travelled in 1688 through the Tartar deserts, with a Chinese embassy, to the banks of the Selingha, there to settle with the Russians the respective limits of the two empires; and having been also in the practice of following the emperor in his hunting expeditions into Tartary, he contributed with other travellers to illustrate the geography of these countries and the manners of the people.

The great extension of the British conquests in Northern India has laid open to Europeans all that portion of Asia which lies on the southern declivity of the Himalaya Mountains, which is interesting not only from its natural grandeur, but also as it contains the sources of the Indus, the Ganges, and the Brahmapootra. The Europeans were indebted for all the knowledge which they possessed of those countries to the Chinese missionaries, who represented the Ganges to rise on the north of the Himalaya chain, from two small streams which pass the town of Ladak. They fixed the source of the Indus in the Beloor Mountains, one of the cross ridges which run north and south from the main Himalaya ridge. The British in India, with all their characteristic ardour in the cause of science, have corrected those errors of the Chinese geographers, having ascertained the source of the Ganges to be not on the north, but on the southern side of the Himalaya Mountains. The extent and bearing, and the vast elevation, of many of the highest peaks of this northern barrier of Hindostan, have also been fixed by the accurate observations of Lieutenant Webb and other officers. From the embassy of Elphinstone into Afghanistan we have received more full details of that country; and the course westward of the great Himalaya chain has been accurately traced, as well as the upper course of the Indus, though the source of that river is still imperfectly known. The missions of Turner into Bootan, of Kirkpatrick and Buchanan into Nepaul, and the embassy of Major Symes and Dr Buchanan to the court of Ava, and of Mr Crauford, who resided in the character of ambassador at that court, and whose works have thrown great light on the commerce and manners of Asia, have contributed materially to illustrate the geography of those countries. Of the vast regions of Tartary to the west of China, and under its dominion, we know nothing except from the earlier travellers and missionaries, and from the accounts published of the journeys of the Russian embassies through these countries; nor is there any immediate prospect of reaching those central districts from the south; for though the inhabitants appear mild and friendly, the Chinese authorities are firm in repressing the slightest intrusion of strangers into the sacred territory.

Asiatic

commerce.

Asia, notwithstanding the wars by which it has been desolated, was from an early period the seat of commerce and of wealth. The eastern countries of Hindostan and China appear to have preceded Europe in civilization and industry, and, independent of that diversity of natural productions which is the foundation of trade, they had culti-

Asia.

vated many arts and manufactures which were unknown in the western world. Asia accordingly abounded in many precious commodities which could not be produced by the ruder industry of Europe. Thus China had its silk and porcelain; Hindostan its muslins, cotton, precious stones, and aromatics of all sorts; costus, bdellium, spikenard, ivory, tortoise-shell, pepper, &c. These were in general demand throughout Europe, where they could not be produced; and they were procured in exchange chiefly for bullion, which then, as in later times, was the great article of export to India; also for woollen cloths, wine, brass, lead and tin, glass, coral, female slaves, &c., all which commodities met with a ready sale in the markets of Hindostan. The staple commodity of China was silk; and the mode of producing this esteemed luxury being unknown in Europe, it was brought in large quantities, either by the caravans or by the annual fleets, to Alexandria, at that time the great commercial mart of the East, and was thence sent to supply the demand at Rome, where it sold at one time for its weight in gold; but, owing to the high profit, caravans began to travel so regularly to China, that the supply increased with the demand, and the price was reduced. Between the 6th and the 7th centuries Eastern Asia was robbed of this precious monopoly by the art of two Persian monks, who contrived, in a hollow cane, to transport the eggs of the silk-worm from China to Europe, where they were hatched by means of heat, and the race quickly propagated; and one great link of commerce between China and Europe was in this manner broken. The trade of Asia was interrupted by the irruption of the barbarians, who invaded and finally subverted the Roman empire; but the moment the storm was past, commerce resumed its quiet course. Constantinople, the eastern capital of the empire, was still the centre of luxury and trade; as were also such parts of the Roman territory as had not been swept by barbarian invasion; and with those places the caravans still traded, shaping their course as they best could to avoid the distractions of the interior. Farther to the east the caliphs who reigned at Bagdad encouraged science, commerce, and the arts; and the extensive country through which the Oxus and the Jaxartes flowed was the seat of a flourishing commerce and of many opulent cities. Besides Buckharia, still a great city, Balk, Samarcand, Cosh, and others in the valley of the Oxus and the Jaxartes, numerous splendid cities are enumerated which are scarcely known to Europeans. To the east of the great range of mountains which takes a direction from the main Himalaya ridge, the country of Cashgar contained Cashgar its capital, and Khoten, which were both large, populous, and wealthy. Those countries served as the connecting link between India and Europe, and the resting-place of the caravans, which there collected in great force, and prepared for their journey to China across the great eastern desert, or for a more southerly course through the country of Thibet. The armies of Zinghis Khan in the 13th, and of Tamerlane in the beginning of the 15th century, laid waste this highly cultivated and flourishing region. But those conquerors were not the enemies of commerce, and the surplus produce of India still reached Europe, though by a route rendered more difficult and dangerous from the desolation of the intervening countries. But the effect produced on the trade of Asia in the East by the encroachments of barbarism, and by the disorders in the interior, was more than counterbalanced by the growing civilization of Europe. About the beginning of the 14th century, the darkness which had so long covered the western world began to dispel, and the Italian cities of Venice, Genoa, and others, had already made advances in letters, science, and commerce. The costly articles of Asia, her rich stuffs and

precious aromatics, were now required to answer the growing demands of luxury and wealth; and the produce of India, imported into Alexandria through the Red Sea, was thence brought into Italy by the nobles of Venice and Genoa, who were all engaged in trade, and was diffused in smaller quantities all over Europe. The Italian states were enriched by this lucrative traffic, which only ceased with the discovery of the maritime route to India by the Cape of Good Hope. From this period the trade between Asia and Europe took a different direction. The commodities of India and China were transported to Europe directly by sea; and neither Alexandria nor the other ports of the Red Sea or of Italy were any longer the depositaries of the eastern trade. The Portuguese, always distinguished by their ardour for maritime discovery, were the first adventurers in the Asiatic seas. In the course of the 16th century the English and Dutch appeared as their competitors; and with the growing wealth of those countries the trade to the East rapidly increased. The commerce of Asia may therefore be distinguished into the following branches:—*1st*, The inland trade of China, Hindostan, Burmah, &c. with Turkey, the eastern countries of Europe, and with the intervening countries of Persia, Balk, Buckharia, and the regions of the Oxus; also, by a different route, the trade with Russia and the north of Asia. *2dly*, The maritime trade, including the coasting trade and the trade to the eastern archipelago, and the great trade to Europe and America, in which, from the progress of wealth and luxury, there is a great consumption of Asiatic produce.

The inland trade of Asia is carried on by caravans, or large bodies of merchants, who travel together for the sake of security through those parts of the country which are disturbed by predatory tribes. It is only from the southern countries of Asia, such as Hindostan, China, the Burmese countries, Thibet, and the western countries of Persia, Afghanistan, Buckharia, and the regions of the Oxus and the Jaxartes, that Europe can derive any supply of valuable commodities; and all this trade, from whatever quarter it comes, must flow in its progress to Europe through the countries that lie between the Persian Gulf and the Caspian Sea; as the caravans could not, without inconvenience and danger from wandering tribes, pass to the north of this sea or the sea of Aral; and accordingly, though an annual caravan is sent from Astracan to Khyvah and the countries on the Oxus, the chief trade with Russia is by sea to the port of Mangalshuck, and thence to Khyvah and Buckharia. The Russians have also begun to trade with Persia from the Caucasian province of Georgia, of which Tiflis, the capital, has, from a wretched collection of wooden huts, been rapidly improved, under the protecting influence of a European government, into a respectable and wealthy town, the future emporium, as may be anticipated, of this growing trade. The caravans from Constantinople and Syria proceed through Asia Minor and the northern or southern provinces of Persia, according as their ulterior route is through Afghanistan and the Punjaub into Hindostan, or to Thibet and China, or the more northern districts of Balk, Buckharia, and the country of the Oxus and the Jaxartes. Buckharia, though reduced to desolation by Zinghis Khan, is still one of the largest towns of the East, and is only exceeded by Peking and other Chinese cities, or by Calcutta. It is also a great commercial mart; and the caravans which come from the west, passing along the southern shore of the Caspian Sea through the Persian province of Astrabad, a most luxuriant and fertile coun-

try, arrive successively at Balfroosh, Ashruff, Astrabad, Mushed, Serrukhs, Merve, formerly the capital of the Seljook sovereigns, but now surrounded by deserts, and at Buckharia. From this great centre of commerce they proceed north-eastward about 400 or 500 miles to Khojend and Kokaun, the former a large city, said to contain 30,000 houses; and crossing the Beloor range of the Himalaya Mountains, they arrive in the Mahometan states of Kashgar and Yarkund, 600 miles east of Kokaun, passing some towns on the way, of which Ush is the most important, being a trading and populous town. Those two latter states lie within the precincts of the Chinese authority, where the most exact order is enforced; and they are fertile, rich, and well cultivated. The town of Cashgar is said to contain 20,000 houses, and to be thronged with strangers from all parts of Asia. Yarkund is also wealthy and populous. So strict a police is maintained by the Chinese authority, that, according to the information given to Fraser,¹ a single traveller may traverse the whole territory as safely as a large caravan. From Kashgar there is a constant intercourse through Chinese Tartary, along the edge of the great central desert, with China, though we know little of the intervening countries beyond what we learn from the accounts of the early missionaries. Besides this eastern trade, and the trade westward along the southern shore of the Caspian, two caravans, consisting of 4000 or 5000 camels each, proceed to Astracan by Khyvah, round the northern shore of the Caspian Sea. The imports from Russia into Buckharia are iron, steel, copper, brass, quicksilver, vermillion, coral, hardware, plated goods, gold and silver embroidery, copper-wire; furs, the broad cloths and cotton manufactured goods of Britain, Germany, and France; refined sugar, cochineal, paper, and a variety of rich goods, which, from this great commercial depot, are diffused far and wide over Central Asia. Russia receives in exchange black lamb-skins, certain manufactures of cotton and silk imported from Persia, antique gems and coins, lapis lazuli, rubies, and turquoises, which are received from the southern country of Buducksha, where there are famous mines of these precious stones. From Cashgar, Yarkund, and the side of China, Buckharia receives large quantities of tea, the great modern staple of the China trade, porcelain and China ware, and the various manufactures of China; and in return sends turquoises, coral, sheep, lamb, and fox-skins, and furs, &c. From Persia shawls are imported, and woollen goods from Kerman; silk stuffs from the cities of Yezd and Ispahan; gold and silver embroidery, copper-ware, loaf, candy, and raw sugar; Hamadan leather; and turquoises, of which there are mines in Persia; and, in return, black sheep and lamb-skins are sent, which are in great request, to be manufactured into black caps; camblet made of camel's hair, coarse coloured silk handkerchiefs, lapis lazuli, indigo from India, cochineal, tobacco, chintzes from Masulipatam, and cotton manufactures. Slaves form a staple article in the commerce of Buckharia, and also of Khyvah. These are made prisoners by the disorderly tribes of Asia, the Koords, Turkomans, &c., in the course of the wars in which they are constantly engaged; and they are carried to the great slave markets of Buckharia and Khyvah, where they are exposed for sale like cattle. The balance of trade is always in favour of Buckharia. Money is consequently in great plenty, and cannot be imported with a profit into this trading city. The Russian caravans, as they journey round the north shore of the Caspian Sea, are frequently attacked by the Kirgeesh and Cossack tribes, and prisoners

¹ Narrative of a Journey into Khorassan, Appendix.

Asia.

are carried off and sold into slavery. Fraser was assured that the number of Persian slaves in Khyvah and its dependencies exceeded the male population of these countries, and amounted to 150,000; and that, according to inquiries set on foot by the empress Catherine, there were in Buckharia no less than 60,000 Russian slaves.

The commerce of the west with the southern countries of Asia, namely, Cabul or Afghanistan, Cashmere, and India, passes through Persia by a different and more southerly route, namely, by Cashan, Yezd, which is the seat of rich silk manufactures, a great entrepôt of commerce, and a convenient resting place for all the caravans, both from the east and other quarters; through Furrah, and Herat, on the frontiers of Persia, famed for its rich manufactures of silk stuffs, a great channel of communication between the east and the west, and also an entrepôt of all the richest productions from Cabul, Cashmere, and India on the one side, and from Buckharia, Persia, Arabia, Turkey, and even Europe, on the other. From Herat the route continues through Furrah and across the river Helmund and the ranges of the Paropamisian Mountains, to Candahar, a journey of about 800 miles; thence to Cabul, Peshawer, and the countries on the Indus, and across extensive sandy deserts to the rich valley of the Ganges, whence, by this river, there is an easy access to Bengal and to Central India. There are various other routes by which the commerce of Asia, concentrated within the comparatively narrow boundaries of the Caspian Sea and the Persian Gulf, diverges in its progress eastward to the north, as well as to the south. From Buckharia there is a mountainous route into Little Thibet, and thence through Thibet into China; besides other more sequestered and difficult roads, through glens and mountains, where the only mode of transport is on the backs of asses and mules.

Persia, from its central situation between the east and the west, is not only a great entrepôt of Asiatic trade, but, though on the whole rather a poor country, it still contributes some valuable productions to the commerce of the East. It has long been famed for its abundant produce of raw silk, of cotton, and of wool, that of the province of Kerman especially being so valuable for shawls that it rivals in some respects that of Cashmere; of fruits, turquoises, tobacco, grain, &c. Almost all the principal towns of Persia, such as Kashan, Ispahan, Yezd, Tabreez, Kerman, Herat, &c. excel in the manufacture of silks, cottons, woollens, fine carpets, &c.; Kerman also in the manufacture of shawls; and others in that of cutlery, arms, &c. These are its chief exports to other countries, in exchange for their manufactures or produce. To India Persia sends raw silk, carpets, Kerman shawls, dried fruits, tobacco, horses, in which there is a considerable traffic, swords, &c. and specie to make up the deficient balance. The imports from India are cotton goods, as chintzes, sent from Masulipatam by sea to Bushire, whence they reach the interior of Persia, and are thence carried eastward into Cabul and the countries on the Indus; the same article from Moultan, Lucknow, Delhi, &c.; some muslins, indigo, spices, sugar, and sugar-candy, in large quantities; gold and silver stuffs and brocades from Benares; precious stones, Cashmere shawls, iron, lead, copper, &c. Many of these articles, namely, Cashmere shawls, spices, indigo, muslins, &c. are carried through Asia Minor by a long land carriage to their final destination in European Turkey, and are found, along with the lamb-skins of the no less distant Buckharia, in the bazaars of Bagdad and

Constantinople.¹ To those countries Persia exports also every article of her own rude and manufactured produce; coarse fabrics, both of silk and cotton, for the consumption of Asia Minor; and many heavy articles, such as grain, rice, tobacco, salt, coffee, cotton, &c.; besides fine silks, brocades, and prints, which are exchanged in Turkey for European goods brought through the countries of the Levant, namely, broad and narrow cloths, cassimeres, cotton goods, chintzes, muslins, veils, silks, satins, French brocades and embroidered goods, imitation shawls, cutlery of all sorts, glass, &c., and a considerable quantity of gold and silver bullion. Persia imports coffee and pearls from Arabia, in exchange for wheat, dried fruits, and cloaks. The mountainous country of Afghanistan, on the southern declivity of the Himalaya ridge, and the country on the head streams of the Indus, export to India horses and ponies bred in Tartary, furs, shawls, Moultan chintz, madder, assafetida, tobacco, and dried and other fruits, such as almonds and pistachio nuts. The imports from India are coarse cotton cloths, worn by the common people of this country, and also in Tartary; muslins and other fine manufactures, silken cloth and brocade, indigo in great quantities, ivory, chalk, bamboos, wax, tin, sandal wood, almost all the sugar which is used in the country, and spices from the Malabar coast, through Koratchee and other parts of Sinde, and thence to Cabul and Candahar. The Indian cloths, shawls, chintzes, and also the indigo, are exported to Buckharia, from which are imported the broad cloths, cutlery, and hardware of Europe, received from the Russians, and finally consumed in Cabul and the countries of the Indus, loaded with the expenses of a land journey across nearly half the globe.

In the east of Asia, China has from the earliest times been the seat of wealth and of an extensive trade. The Chinese have been always noted for their industrious habits, and the country has from time immemorial abounded in the most valuable produce and manufactures. These were sent westward in the caravans to Asia Minor and into Europe, or they were transported by sea to India, and carried thence by the European fleets to the Red Sea. The same commerce is still continued, and China exports its produce of woollens, silk, and satin; tea in small boxes of thin lead; china, porcelain, raw silk, cochineal, crystal, gold dust, golden ingots, and silver with the Chinese stamp. These are sent through Chinese Tartary into the countries on the Oxus, and also to Cashmere, Cabul, and the countries situated on the southern declivity of the Himalaya Mountains. Regular caravans of horses and ponies, no other animal being fit to travel through those mountainous districts, set out from Cashmere, and from Peshawer, the capital of the Afghan country of Cabul, and a considerable commercial resort, to make their way through Chinese Tartary with goods imported from India and Persia. China carries on also an interior trade to a considerable extent with Russia by the frontier town of Maimatchin, in which European goods and furs are received in exchange for tea, silk, and other articles of Chinese produce and manufacture.

In addition to her internal trade, Asia maintains an extensive intercourse by sea with Europe, America, and with Egypt and all the countries on the Mediterranean. A great trade is also carried on from Hindostan and China to the Asiatic archipelago, and the trade of the Asiatic islands with each other is of great importance. It appears that those islands were at a very early period the seat of commerce; and the learned researches of Europeans have brought to light, in some of them, the monuments of ancient

¹ Elphinstone's *Cabul*; Kinneir's *Geographical Memoir of Persia*; Fraser's *Travels in the Persian Provinces around the Caspian Sea*, Appendix, p. 364.

civilization. Sumatra was the seat of the Malay empire, Java of a Hindoo state; and the Celebes were inhabited by the Bugis, a race of expert navigators and merchants. The productions of these islands, and of the Moluccas and Borneo, namely, spices, aromatics, and gold, entered into the commerce of the ancient world, and were imported into Rome through Egypt. In later times, about the 9th century, the Asiatic archipelago was visited by the Arabs and the Chinese, while the adventurous Malays frequented the coasts of Asia, and even of Africa, and particularly the African island of Madagascar. When these islands were visited by Europeans, about the 15th century, Malacca, Acheen, and Bantam were the great marts of the eastern archipelago, where the rich produce of Sumatra, Borneo, and the Moluccas, conveyed in the small trading craft of the country, was exchanged for that of India and China. The Portuguese fixed on Goa, on the Malabar coast, as the capital of their eastern settlements; and they afterwards selected Malacca as a central station for protecting and extending their intercourse with the neighbouring nations. The Dutch chose Bantam, and afterwards Batavia, situated midway between Hindostan and China, as the centre of their commercial settlements. The situation was most advantageous, and the port was soon frequented by vessels from China and Japan, Tonquin, Malacca, Cochin-China, and the island of Celebes. But the great and flourishing trade of Java was crushed under the colonial monopoly of the Dutch, and under what Sir Stamford Raffles terms "the short-sighted tyranny of a mercantile administration." The conquest of Java by the British in 1812 put an end to this thralldom, and the great trade of the Asiatic archipelago began to centre in Batavia, which was fast rising into a great commercial emporium; all the articles which were the exclusive produce of the eastern islands being collected at its principal ports for re-exportation to India, China, and Europe. Since Java was restored to the Dutch, the free port of Singapore, established by the British, is the centre of a great trade, and is frequented by the Chinese in their junks, and by all the other navigators of those seas with the produce of their respective islands.¹ The Chinese take back with them the nests of a certain species of bird, which are esteemed a great luxury at their tables, and sell, it is said, for their weight in silver; biche-de-mer or tripang, a dried sea-slug, also used in Chinese dishes; Malayan camphor, the exclusive produce of Sumatra and Borneo; the tin of Banca, the spices of the Moluccas, opium, indigo imported from Hindostan; gold and silver, the first collected in Sumatra, Borneo, and some of the other islands. The maritime country trade of the Asiatic islands is carried on chiefly by the Chinese in their junks and brigs, by the Arabs in square-rigged vessels, and by the Bugis, the inhabitants of Celebes, who are all bold and expert navigators.

From the east the annual fleet of Chinese junks arrives with the favourable monsoon among these islands, from Canton, Amoi, and other provinces, with cargoes of teas, raw silk, silk, piece-goods, and innumerable minor articles, for the use of the Chinese, who are settled in great numbers here, and are distinguished by their shrewd, intelligent, and industrious habits. The Chinese extend their voyages to Sumatra, the Straits of Malacca, and eastward as far as the Moluccas and Timor, collecting edible bird-nests, biche-de-mer, and other articles of which Java is the great entrepôt. Java is also a great dépôt of European goods; and the people being rather industrious culti-

vators of their fertile island than mariners or traders, it exports rice, a variety of vetches, salt, oil, tobacco, timber, brass-wire, and its own cloths, and a considerable quantity of European, Indian, and Chinese goods, in exchange for gold dust, diamonds, camphor, benjamin, and other drugs; edible bird-nests, biche-de-mer, rattans, bees-wax, tortoise-shell, and dyeing woods from Borneo and Sumatra. The rice and other productions of Java are exchanged for spices and pungent oils of the Moluccas, and for the tin of Banca. The natives of Celebes are famed for the manufacture of a particular species of fine cloths, of a very strong texture, which are in great request, and, along with spices, wax, and sandal-wood, are exchanged for the produce of Sumatra, Borneo, and Java, whence they are exported to China. The Bugis have a large share of the carrying trade of the Asiatic archipelago; and they bring the produce of the Moluccas, and of Borneo and Sumatra, to Java and the other islands, and receive in exchange tobacco, rice, and salt, from Java, besides opium, iron, steel, European chintzes, and broad cloths and Indian piece goods, with which they return eastward during the southwest monsoon.²

The eastern countries of Asia, viz. India and China, as we have already stated, have from time immemorial been famed for certain manufactures, such as silks, cambrics, muslins, &c., as well as for other products peculiar to the climate, viz. spices, precious aromatics, medicinal herbs, &c. These were always in great demand in Europe, while the produce of Europe was not wanted in Asia. From the rude state of industry among the western nations, they had nothing to offer in exchange for the finer manufactures of India, and still less could the soil of Europe yield any equivalent for the more genial produce of eastern climes. Hence the great article of export in those times from Europe to Asia was always bullion, the instrument of exchange all over the world. Bullion could only be procured by an exportation of European produce or manufactures at such low prices as to insure a sale; and the loss on such transactions must have been made up to the merchant by the high price of Asiatic goods. The ancient monopoly of silk secured to Asia a favourable balance of trade with Europe, bullion being the only article with which it could be purchased. Notwithstanding the introduction of the silk manufacture into Europe about the 6th or 7th century, the commercial pre-eminence of Asia still continued, and bullion was the chief article of export to the East. Throughout the interior of Asia this superiority remains to the present day; and a continual stream of bullion flows from the Bosphorus eastward through Asia Minor and Persia into Hindostan, and is finally dispersed in the great ocean of the Chinese currency. Bullion is also the principal article sent from Arabia to India in exchange for Indian goods.

But a great revolution has taken place in the trade between Asia and Europe, and especially with Great Britain. Europe is now in a condition to offer an equivalent in manufactures for the produce of Asia; goods of various kinds are sent in exchange for those of India; and from Great Britain remittances in bullion have nearly ceased. So prodigiously has the price of goods been lowered by the use of machinery, that the cotton wool of India is now imported into Britain, and, after being manufactured, is re-exported to the place of its growth, and sold at a lower price than the same goods from the loom of the Indian workman, though it is loaded with the expense of a double voyage across half the globe. The goods of the Eu-

Asna.

European manufacturers are poured into Asia through all its seaports, and reaching the interior on the backs of mules and asses, often after a journey of several thousand miles over deserts and mountains covered with perpetual snow, they are sold cheaper than the same articles by the native workmen. The woollen manufactures of Yorkshire, the cotton goods of Manchester and Glasgow, French cloths, and German linens, are dispersed all over Hindostan, and even partially in China; they are found in the bazaars of Buckharia, Samarcand, and Cashgar, and are carried eastward by the caravans into the wilds of Tartary.¹ The accounts laid before the House of Commons of our exports and imports to and from India and China from 1814 to 1828, exhibit a falling off in the importation of Indian manufactures, and a proportional increase in that of the raw materials, such as silk, cotton, indigo, &c. From India and China the annual value of the imports amounts to about L.10,000,000. In 1829 they amounted in value to L.10,627,441; of which the sum of L.8,561,345 is made up of four articles, viz. cotton wool, indigo, raw silk, and tea.² The value of the cotton manufactures exported, which amounted in 1814 to L.11,341, had increased in 1828 to L.754,098. The natural productions of Asia, namely, spices, rich aromatics, dyes, and other rare luxuries of tropical climates, will always be in demand in Europe; and the monopoly of tea by the Chinese gives them the command of the European markets. Tea has now almost become one of the necessities of life, and it travels for a market across half the globe. It is the great commercial

link between Europe and China, from which, like the precious produce of silk in ancient times, it can only be procured. But the improved industry of Europe supplies, as already observed, an equivalent in woollen and cotton goods for this highly prized luxury; and there can be no doubt that if the trade were not obstructed by the East India Company's monopoly, it would gradually extend with the growing demand of the Chinese market. The charter of the East India Company expires in 1834; and if the trade is thrown open, it is certain that British produce will make its way into all the most distant markets of the East. Such an intercourse would not only benefit commerce, but would promote the higher interests of civilization, as it would extend to the benighted countries of Asia the literature and science, and all the other improvements, of Europe.

ASIA MINOR is the most western portion of the great continent of Asia, bounded by the Black Sea on the north, by the river Euphrates on the east, and on the west by the Mediterranean, the Sea of Marmora, and the Straits of the Hellespont and Bosphorus. It is of an irregularly oblong figure, about 1000 miles in length from east to west, and between 400 and 500 in breadth from north to south. The whole country is under the Turkish government; and it is divided into several provinces, of which Natolia and Caramania are the most important. The country is inhabited by Turkish Mahometans, and Christians of various sects and denominations. For other particulars see the preceding article. (F.)

ASIARCHÆ (termed by St Paul, *Chief of Asia*, Acts xix. 31) were the Pagan pontiffs of Asia, chosen to superintend and have the care of the public games, which they did at their own expense; for which reason they were always the richest and most considerable men of the community.

ASINARA, an island of Italy, on the western coast of Sardinia. Long. 8. 30. E. Lat. 41. 0. N.

ASINIUS POLLIO, a Roman consul and orator, distinguished himself under Augustus by his exploits and his literary works. He is frequently mentioned with praise by Horace and Virgil, and is said to have collected the first library at Rome. He died at Frescati, at eighty years of age.

ASISIO, or ASITO, a city of the pope's territories in Italy, situated about 16 miles east of Perugia. Long. 13. 35. E. Lat. 43. 0. N.

ASKEATON, a post town of Ireland, in the county of Limerick, on the river Deal, near its junction with the Shannon. Population 1239. 144 miles S. W. from Dublin.

ASKEREN, a place five miles from Doncaster, noted for a medicinal spring of a strongly sulphureous nature; it is also slightly impregnated with a purging salt.

ASKRIG, a town in the North Riding of Yorkshire. Long. 0. 5. W. Lat. 53. 50. N.

ASLANI, in *Commerce*, a silver coin, worth from 115 to 120 aspers.

ASMONEUS, or ASSAMONEUS, the father of Simon, and chief of the Asmoneans, a family that reigned over the Jews 126 years.

ASNA, or ESNA, a town in Upper Egypt, seated upon the Nile, and occupying the site of the ancient Latopolis. It is near the cataracts of the Nile, and is the last place

of any magnitude on the side of Nubia. It contains several monuments of antiquity, and among the rest an ancient Egyptian temple, pretty entire, all painted throughout, except in some places that are effaced by time. The columns are full of hieroglyphic figures. This structure is considered by Denon as one of the most perfect monuments of ancient architecture he had seen. A little way from thence are the ruins of an ancient nunnery, said to be built by St Helena, surrounded with tombs. Asna is the principal town in these parts, and the inhabitants are rich in corn and cattle. They drive a considerable trade into Lower Egypt and Nubia, by means of the Nile, and also by the caravans that pass over the desert. The inhabitants are all Arabs, except about 200 Copts, the ancient inhabitants, and a sort of Christians. They are under the government of the Turks, who have a *cadi*; and the Arabs have two sherifs of their own nation. Long. 32. 35. E. Lat. 23. 15. N.

ASOLA, a town of the territory of Brescia, in the Austrian division of Italy. It is built on the river Chiese, about 20 miles south-east from Brescia, and contains a population of 3100 persons. Long. 10. 35. E. Lat. 45. 6. 4. N.

ASOLO, a town of Austrian Italy, in the delegation of Verona, on the river Musone. It is well built and finely situated. It has a cathedral and several other churches, with an ancient castle, and the remains of a Roman aqueduct. The inhabitants are mostly employed in cultivating silk. Long. 12. 1. 5. E. Lat. 45. 47. 37. N.

ASOPH, a town of Cuban Tartary, in Asia, seated on the river Don, near its mouth, a little to the east of the Palus Mæotis or Sea of Asoph. Long. 39. 5. E. Lat. 47. 18. N.

¹ Mr J. Burnes, surgeon to the residency at Booj, who has lately published an interesting *Narrative of a Visit to the Court of Sind*, mentions that the princes and nobles are clothed in British manufactures. He resided at Hyderabad in 1827.

Asoph.

ASP, in *Natural History*, a small poisonous kind of serpent. It is said to be thus denominated from the Greek *ασπις*, a shield, in regard to the manner of its lying convolved in a circle, in the centre of which is the head, which it exerts or raises like the umbo or umbilicus of a buckler. This species of serpent is very frequently mentioned by authors, but so carelessly described that it is not easy to determine which, if any, of the species known at present may properly be called by this name. It was with the asp that Cleopatra is said to have dispatched herself, and prevented the designs of Augustus, who intended to have carried her captive to adorn his triumphal entry into Rome. But the fact is contested: Sir Thomas Brown places it in the list of vulgar errors. The indications of that queen's having used the ministry of the asp were only two almost insensible pricks found in her arm; and Plutarch says that the cause of her death is unknown. Lord Bacon makes the asp the least painful of all the instruments of death. He supposes it to have an affinity to opium, but to be less disagreeable in its operation. See REPTILIA.

ASPASIA OF MILETUS, a celebrated courtesan who settled at Athens under the administration of Pericles. She was of admirable beauty: yet her wit and eloquence, still more than her beauty, gained her extraordinary reputation among all ranks in the republic. Her conversation was so entertaining and instructive, that notwithstanding the dishonourable commerce she carried on in female virtue, persons of the first distinction, male and female, resorted to her house as to an academy. It is said that she even numbered Socrates among her hearers. She captivated Pericles in such a manner that he dismissed his own wife in order to espouse her; and by her universal knowledge, irresistible elocution, and intriguing genius, she in a great measure influenced the administration of Athens. She was accused of having excited, from motives of personal resentment, the war of Peloponnesus. The companions of Aspasia served as models for painting and statuary, and themes for poetry and panegyric. Nor were they merely the objects, but, as is said, the authors, of some literary works, in which they established rules for the behaviour of their lovers, particularly at table; and explained the art of gaining the heart and captivating the affections.

ASPASTICUM (from *ασπαστικον*, *I salute*), among ecclesiastical writers, a place or apartment adjoining to the ancient churches, wherein the bishop and presbyters sat, to receive the salutations of the persons who came to visit them, desire their blessing, or consult them on business. This is also called *aspasticum diaconicum*, *receptorium*, *metatorium*, or *mesatorium*, and *salutatorium*; in English, *greeting-house*.

ASPER, in *Grammar*, an accent peculiar to the Greek language, marked thus (´), and importing that the letters over which it is placed ought to be strongly aspirated, or pronounced as if an *h* were joined with them.

ASPER, or *Aspre*, in *Commerce*, a Turkish coin, three of which make a medine.

ASPERIFOLIATE, or ASPERIFOLIOUS, among botanists, such plants as are rough-leaved, having their leaves placed alternately on their stalks, and a monopetalous flower divided into five parts.

ASPEROSA, a town of Turkey in Europe, situated on the coast of the Archipelago. It is a bishop's see. Long. 25. 20. E. Lat. 40. 58. N.

ASPHALTITES, or LAKE OF BITUMEN, so called from the bitumen which floats upon its surface, and

equally well known under the name of the DEAD SEA, a name associated with many fables, and derived from a long standing belief that no creature could live in its waters, or within the reach of its pestiferous exhalations.

Very different accounts have been given of the dimensions and other properties of this lake, by the ancient writers Diodorus, Pliny, Strabo, and Josephus. These accounts have, however, been corrected by modern travellers, although, from the difficulty of approaching it, their information is not so full or accurate as might be desired. Pliny estimates it to be 100 miles in length by 25 in breadth. Josephus reckons the length, from the mouth of the Jordan to the town of Segor, 66 miles, and the breadth 15 miles. This agrees with the estimate of modern travellers, which is 60 or 70 miles in length and from 10 to 20 in breadth. Carne, in his *Letters from the East*, estimates the length at 60 miles, and the breadth at from 8 to 10. It is about 180 miles in circuit. In form it is curved like a bow, and placed between two ranges of mountains, bold and craggy, and of the most majestic appearance, by which it is sheltered, so that when the wind is blowing all around it is perfectly calm like a sheet of lead. But the grandeur of its features is blended with an air of sadness and desolation, and all travellers have been struck with the death-like stillness of its waters, which seem to accord well with its mysterious character and name. This lake has been seldom visited, owing to the wild Arabs who inhabit the country, and who rob and murder without mercy the defenceless traveller. Mr Buckingham, who had only a distant view of it, mentions that the inhabitants who live within 15 miles distance of its shores have no information respecting it, and believe in all the wonderful tales and superstitions which are circulated of its marvellous properties. It was since visited by Mr Carne, whose Letters contain a lively picture of eastern scenery and manners; and his representation of the death-like stillness of this lake and the adjacent country agrees with that of all former travellers. "There was not," he observes, when he visited it, "a breath of wind; and the waters lay dead on the shore. Whoever has seen the Dead Sea will have its aspect impressed on his memory. It is in truth a gloomy and fearful spectacle. The precipices in general descend abruptly into the lake, and on account of their height it is seldom agitated by the winds. Its shores are not visited by any footstep save that of the wild Arab, and he holds it in superstitious dread. On some parts of the rocks there is a thick sulphureous incrustation, which appears foreign to their substance; and in their steep descents there are several deep caverns, where the benighted Bedouin sometimes finds a home." The same writer observes, that though the sun shone full on the bosom of the lake, and though it had the appearance of a plain of burnished gold, yet "the sadness of the grave was on it and around it, and the silence also. However vivid the feelings are on arriving on its shores, they subside after a time into languor and uneasiness; and you long, if it were possible, to see a tempest wake on its bosom, to give sound and life to the scene."¹

The lake Asphaltites receives the waters of the river Jordan, and other brooks and springs from the adjacent mountains, yet never overflows, though it has no visible outlet for those copious supplies. This fact seems to have embarrassed some naturalists, who, in order to account for it, have had recourse to the hypothesis of a secret communication with the Mediterranean. But it has been demonstrated by accurate calculation, that evapora-

Asphaltites.

Asphal-
tites.

tion is more than sufficient to carry off the waters brought by the river. Under the influence of a dry and hot climate, it is in fact very considerable, and frequently becomes sensible to the eye by the fogs with which the lake is covered at the rising of the sun, and which are afterwards dispersed by the heat. To the north it has the plain of Jericho, and to the south extends, on both sides of the Jordan, the great plain, which is open, and stretches beyond the reach of the eye. It is this plain of which, according to Mr Buckingham, Josephus gives so accurate a description.

This lake is supposed to occupy the site of the cities of Sodom and Gomorrah, destroyed by fire, as is recorded in the sacred volume, for their unparalleled iniquities; and the strange properties ascribed to its waters, and other marvellous stories connected with it, seem to have a reference to this awful tradition. It was at one time supposed that no living creature could exist in its waters—that they exhaled such a poisonous effluvia that the birds of the air died in attempting to fly over it. The apples that were said to grow on its shores, fair without, but full of ashes and bitterness within, were also supposed to contain some moral or illustration of its ancient story; and it was affirmed that the ruins of the five cities which were destroyed by fire were still seen at the bottom of the lake in clear weather. Josephus mentions that a constant smoke was seen to arise from its surface. Almost all these stories have been exploded by the testimony of modern travellers, although some of them have an obvious foundation in the physical properties of the waters. Their taste is remarkably bitter, saline, and pungent; and hence has arisen the notion of its pestiferous vapours and deadly influence. We are told even by Volney, that its waters are destructive both of animal and vegetable life; but he denies that its vapours have any deadly quality, for swallows, he says, are often seen to skim its surface without injury. M. de Chateaubriand, who visited its shores in 1807, with an imagination abundantly disposed to the marvellous, has given the first decided testimony that it abounds in fish. He reached the lake when it was already dark, and passed the night among some Arab tents. "About midnight," says he, "I heard a noise upon the lake, and was told by the Bethlehemites who accompanied me, that it proceeded from *legions of small fish* which come out and leap about on the shore." This interesting traveller speaks in the following terms of its saline properties:—"The first thing I did on alighting was to walk into the lake up to my knees, and to taste the water. I found it impossible to keep it in my mouth. It far exceeds that of the sea in saltiness, and produces upon the lips the effect of a strong solution of alum. Before my boots were completely dry, they were covered with salt; our clothes, our hats, our hands, were in less than three hours impregnated with this mineral."

The common story, that nothing will sink in it, is to be ascribed to the extraordinary density of its waters. Bodies follow the general law, and sink or swim, according to the proportion of their gravity to the gravity of the water of the lake; but its specific gravity is such that a man may lie upon its surface motionless, without danger of sinking. This effect was experienced by Pococke, and by a Scottish traveller, Mr Gordon of Clunie, who also bathed in it. This gentleman brought home a phial of its water, and Dr Marcet found its specific gravity to be 1.211; "a degree of density," says he, "not to be met with in any other natural water." Dr Marcet was employed to analyse Mr Gordon's specimen, which that gentleman had presented to Sir Joseph Banks in 1807; and the whole process, with its results, is detailed in the *Philosophical Transactions* for that year. It was found

that 100 grains of the water contains the following substances, in the under-mentioned proportions:—

	Grains.
Muriate of lime	3.920
Muriate of magnesia	10.246
Muriate of soda	10.360
Sulphate of lime	0.054
	24.580

The water of the Dead Sea had been previously analysed by Messrs Macquer, Lavoisier, and Sage, of whose experiments an account was published in the *Mémoires de l'Académie des Sciences* for the year 1778. Their analysis afforded results greatly different from those obtained by Dr Marcet, which that gentleman ascribes to some inaccuracy in their mode of operating. We find, however, that the processes employed by Dr Marcet have been called in question, and the accuracy of his proportions denied, by a very skilful chemist, who subsequently instituted an analysis of the Dead Sea water. We allude to Klaproth, who procured a specimen brought from the East by the Abbé Mariti, and whose analysis offered the following proportions:—

Muriate of magnesia	24.20
Muriate of lime	10.60
Muriate of soda	7.80
	42.60
Water	57.40

100

Klaproth also found the specific gravity to be 1.245 instead of 1.211; agreeing in this respect more nearly with Macquer and Lavoisier, who stated it at 1.240. The specific gravity of Dr Marcet's specimen may, however, have been less from its having been taken from the lake not far from the influx of the Jordan, on which account it might be somewhat diluted.

Dr Clarke mentions that the inhabitants of the country still regard the Dead Sea with feelings of terror. This may be owing to the tradition that its waters cover the engulfed cities of Sodom and Gomorrah, or to the ideas entertained of the peculiar insalubrity of its exhalations. It is much to be regretted that this traveller was prevented by the Arabs, who infested the neighbourhood, from exploring the lake, which he only saw at some distance; as, with his attainments, he could not have failed to gather some interesting information regarding its natural history. Though M. de Chateaubriand, a few years after, succeeded in reaching its banks, he could only, owing to the same cause, remain a few hours; and besides, however capable of interesting his readers, he was not so well qualified for accurate or scientific observation. While some of his facts run counter to the ancient fables, others seem calculated to add to the list; as, when he discovers a resemblance between the noise of its waves and the stifled clamours of the people whom they engulfed. (See Chateaubriand's *Travels in Greece, Palestine, Egypt, and Barbary*; Dr Clarke's *Travels in Greece, Egypt, and the Holy Land*; *Philosophical Transactions of the Royal Society of London* for 1807; Klaproth, *Beiträge zur Chemischen Kenntniss der Mineral Körper*, book v. p. 185, Berlin, 1810; Buckingham's *Travels in Palestine*; Carne's *Letters from the East*.)

ASPHALTUM, BITUMEN JUDAICUM, or JEW'S PITCH, is a light, solid bitumen, of a dusky colour on the outside, and a deep shining black within; of very little taste, and having scarcely any smell, unless heated, when it emits a strong pitchy one. It is found in a soft or liquid state on the surface of the Dead Sea, and by age grows dry

Asphal-
tum.

and hard. The same kind of bitumen is met with likewise in the earth in other places of the world, in China, America, and in some places of Europe, as the Carpathian Hills, France, Neufchatel, &c.

ASPHURELATA are semi-metallic fossils, fusible by fire, and not malleable in their purest state, being in their native state intimately mixed with sulphur and other adventitious matter, and reduced to what are called *ores*.

ASPICUETA, or AZPILCUETA, MARTIN DE, commonly called the Doctor of Navarre, was descended of a noble family, and born on the 13th of December 1491, at Varasayn, a small city of Navarre, not far from Pampeluna. He entered very young into the monastery of regular canons at Roncevaux, where he took the habit, which he continued to wear after he left the convent. He studied classical learning, natural and moral philosophy, and divinity, at Alcalá in New Castile, adopting chiefly the system of Petrus Lombardus, commonly called the *Master of the Sentences*. He applied himself to the study of the law at Ferrara, and taught it with applause at Toulouse and Cahors. After being first professor of canon law at Salamanca for 14 years, he quitted that place to be professor of law at Coimbra, with a larger salary. The duties of this office he discharged for the space of 20 years, and then resigned it to retire into his own country. Pope Pius V. made him assistant to Cardinal Francis Aciat, his vice-penitentiary; and Gregory XIII. never passed his door without calling for him, and stopped sometimes a whole hour to talk with him in the street. He was consulted as an oracle; and his name became so famous, that even in his lifetime the highest encomium on a learned man was to call him a *Navarrus*. He died on the 21st June 1586, having by temperance prolonged his life to the age of 94. He wrote a number of treatises on morality, law, &c. These were published in 3 vols. folio in 1589, and in 6 vols. 4to in 1602.

ASS, in *Zoology*. See MAMMALIA.

ASSAI, in *Music*, signifies quick; and, according to others, that the motion of the piece be kept in a middle degree of quickness or slowness. As, *assai allegro*, *assai presto*.

ASSAM, a kingdom of Asia, situated on the north-west of Bengal, between the 25th and 26th degrees of north latitude, and extending from 94 to 99 degrees of east longitude. The exact limits, however, are not precisely ascertained; for this country is very little known to Europeans, and what respects its extent to the east is at present to be understood as partly conjectural. Assam is an immense valley, about 700 miles in length by between 60 and 80 in breadth, surrounded by high hills on all sides, and interspersed with numerous eminences in the interior, and universally susceptible of cultivation. The whole superficies is calculated at 60,000 square miles, a large portion of which is occupied by woods and rivers, and the remainder consists chiefly of fertile soil; but this calculation is exclusive of any conquered countries, and of the territories that extend in every line beyond the hills. Part of the kingdom is mountainous, particularly what is called Higher or Upper Assam; and part of it is low and level, containing extensive plains, subject to frequent inundations in the rainy seasons. The general position of this great valley, as well as of the mountains and rivers traversing it, is in a direction from north to south. It is bounded on the north by the successive ranges of the mountains of Bootan, Anka, Duffala, and Miree; and on the south by the Garrow Mountains, which rise higher as they recede northward, and change their name to Naga at a place called Coliabark. Probably the rivers intersecting Assam are more numerous than those of any other country of equal extent in the universe, from its being

completely environed by hills. The rains are collected together, and, pouring down in irresistible torrents, swell the waters below, until the plains are covered by the inundation. The valley is divided throughout by the Brahmaputra into two parts nearly equal; and many islands, some of them very large, are formed by it and by the confluence and mutual intersection of other rivers. They contribute alike to fertilize the ground and to facilitate the intercourse of the inhabitants, as they are navigable by flat-bottomed boats, capable of transporting them and their property. Of these rivers, not less than sixty-one are known and distinguished by particular names, of which thirty-four flow from the northern, and twenty-four from the southern mountains; but the source of the Brahmaputra is scarcely yet ascertained, nor were Europeans acquainted with its course until it was traced by Major Rennell. However, it seems to rise beyond the confines of Assam. As the rivers change their names at different places, it is sometimes difficult to discover which is meant in the description; and their sizes may be estimated differently, according as they are examined in the time of inundation, or otherwise. Many of them are remarkable for a long and winding course. The Dhekow or Degoo, by the size of which geographers are accustomed to compare the other rivers, rises very far to the eastward of the Naga Mountains, which it traverses for a considerable distance, and then winds 200 miles through the valley from its entrance, until it joins the Dehing, a great branch of the Brahmaputra. Another river, the Dekrungh, rises in the Duffala Mountains, and, exhibiting a large stream, occupies 100 miles in its windings before falling into the Brahmaputra, though the direct line does not exceed 25. Notwithstanding its depth and rapidity, it is navigable by small boats. The river Pisola, which likewise rises in the Duffala Mountains, pursues a winding course of 60 miles, and, during the rainy season, may be ascended to the base of the mountains; but it is not navigable after the inundations subside. The rivers to the south are never so rapid, as the inundations commence from the northern rivers. Both these and the Brahmaputra are filled, so that the water has no considerable current until May or June, when the current is rather stronger from the south in the season of the rains, though the increase is not very material, as the large river at this period is always pretty full, and checks the rapidity of all the southern rivers.

Among the numerous islands of different dimensions formed by the intersection and confluence of the rivers, is Majuli, or the Great Island, as it is called by pre-eminence, which appears to constitute one of the chief political divisions of the kingdom. This island extends 100 miles in length by about 60 in breadth, and is formed by the river Dehing on the west and the Looicheh on the north; but, independently of these great aquatic boundaries, it is intersected by numerous streams, so that it in fact consists of a cluster of lesser islands, and some islets besides, near the banks, which in the principal rivers are dry only while no inundations prevail. The other islands throughout Assam are of all different dimensions, from the most inconsiderable size to six, ten, or twenty miles and more in length. A correct picture of the country may thus be figured as being an extensive valley, environed by mountains, and full of rivers and level plains. While the rivers constitute its defence, promote the convenience of its inhabitants, and contribute to fertilize the soil overflowed by their inundations, they interrupt occasional intercourse from their magnitude and rapidity; and it is to be observed that there is only one stone-bridge in the kingdom, which was erected at Rungpore by workmen brought from Bengal. Besides the Great Island, or

Assam. Majuli, Assam contains other two political divisions, Ootrecole, Uttarcul, or Ootreparah; and Deccancole, Dacshincul, or Deccanparah; the former of which, Ootrecole, denotes the country lying north of the Brahmaputra; the latter, Deccancole, that to the south. And it is farther to be remarked, that Majuli is formed by great arms of the same river, though passing by different names.

The political subdivisions of Assam are apparently almost as numerous as the more important natural ones; but the province of Camroop in Ootrecole is one of the largest, and the best known by description, at least to Europeans. It formerly gave name to an extensive kingdom, of which the capital seems to have been Rangmattee, beyond the present western confines of Assam. It now stretches about 100 miles in length; and its breadth, from the banks of the Brahmaputra to the foot of the mountains, is 40 miles. There are no strong places within its limits, and its chief town is Cotta. The district of Summooria occupies the southern banks of the Brahmaputra; and the district of Nodooaria, which extends to the eastward, is divided into nine shares or districts, held by so many rajahs, though under the rule of only two.

Valuable minerals are found in Assam: the whole country produces gold in abundance, insomuch that from 12,000 to 20,000 of the inhabitants are said to have been constantly employed in collecting it. This precious metal is found in all the rivers flowing from the northern mountains, but it differs in purity and colour, and also in malleability. That which is obtained in the Dekrungh is particularly celebrated, and is distinguished by a higher colour than that found in the Brahmaputra and other rivers. Gold is more abundant in the bed of the Brahmaputra than in the channel of most of the others, but is considered inferior in colour and quality. What is procured from the bed of the Burrowgown is esteemed as much superior even to the gold of the Dekrungh; the colour is deeper and more vivid, and is compared by the natives to fire; it is likewise deemed of more intrinsic value, and always bears a greater price in Assam. The greatest quantities of gold are found nearest the mountains, which probably indicates that it is carried down from them by the torrents; but it is never sought in the beds of the southern rivers. In the others, as those flowing from the north, it is of a paler colour, less pure, and in smaller quantity, according as it is recovered from the mines farther to the east. The persons employed in collecting it pay a small tribute to the sovereign in proportion to their success. Besides this precious metal, there are mines of silver, lead, and iron, which all belong to the king, and are wrought for his advantage alone. Rock-salt is dug out of the earth, but it is bitter, and of indifferent quality. The vegetable products of Assam are abundant, and of excellent quality: thick and extensive forests cover a large portion of the country; cultivated fields, especially of rice, the staple grain for subsistence, and the finest fruits, are generally to be seen. A Persian writer, Mahommed Cazim, in describing this country, makes some observations on its general appearance, which, as he was hostile to the inhabitants, may probably merit the greater confidence. He speaks of Majuli as "an island well inhabited, and in an excellent state of agriculture: it contains a spacious, clear, and pleasant country, extending to the distance of about 100 miles. The cultivated part is bounded by a thick forest, which harbours elephants, and where these animals may be caught, as well as in four or five other forests of Assam. If there be occasion for them, five or six hundred elephants may be procured in a year. Across the Dhonec, which is the side of Ghergong, is a wide, agreeable, level country, that delights the heart of the beholder. The whole face of it is

marked with population and tillage; and it presents on every side charming prospects of ploughed fields, harvests, gardens, and groves. From the village of Salagerah to the city of Ghergong, a space of about 100 miles is filled with such an uninterrupted range of gardens, plentifully stocked with fruit-trees, that it appears as one garden. Within them are the houses of peasants, and a beautiful assemblage of coloured and fragrant herbs, and of garden and wild flowers blowing together. As the country is overflowed in the rainy season, a high and broad causeway has been raised for the convenience of travellers, from Salagerah to Ghergong, which is the only uncultivated ground that is to be seen. Each side of this road is planted with shady bamboos, the tops of which meet and are entwined. Among the fruits which this country produces are mangoes, plantains, jacks, oranges, citrons, limes, and punialeh, a species of amleh, which has such an excellent flavour that every person who tastes it prefers it to the plum. There are also cocoa-nut trees, pepper, vines, areca-trees, and the sadij (an aromatic leaf), in great plenty. Sugar-cane excels in softness and sweetness, and is of three colours, black, red, and white; there is ginger free from fibres, and betel-vines. The strength of vegetation and fertility of the soil is such, that whatever seed is sown, or slips planted, they always thrive. The environs of Ghergong furnish small apricots, yams, and pomegranates; but as these are wild, and not assisted by cultivation and engrafting, they are very indifferent. The principal crop of this country consists in rice and mash. Ades, a kind of pea, is very scarce, and wheat and barley are never sown." This is a favourable picture of the kingdom; and although the revolutions and convulsions which it has since undergone may have affected the industry of the inhabitants, the means of renewing it remain.

Elephants, wild buffaloes, hogs, and tigers, haunt the banks of the rivers, which are covered with grass and reeds so as to be impenetrable by men. It has been affirmed that there are neither horses, asses, nor camels here, though two species of the first are natives of a neighbouring territory. The other animals are unknown, but the rivers abound so plentifully with fish as to afford a copious supply to the inhabitants. A particular kind of animal, different from the common silk-worm, according to Turpin, produces silk of another texture, with which beautiful dresses, but of bad quality, are fabricated.

It is not unlikely that some external physical distinctions prevail among the natives, according as they inhabit the high or the low countries, and that their moral qualities are influenced by the same cause. Mahommed Cazim remarks, that the complexion of the mountaineers, like that of the inhabitants of all cold climates, is red and white. They are an active, hardy race, well formed; but the noses of the women are flattish. Both sexes go almost naked; formerly the mountaineers were absolutely so; and, unlike the easterns in general, none of the females, even those of the highest rank, are veiled. They wear a blue bonnet or cap, from which hogs' teeth are suspended; which is perhaps of more recent use, as the Persian just referred to says they had neither turbans, robes, drawers, nor shoes. Their most valuable ornaments at present are bracelets of coral or yellow amber, and sometimes tortoise-shell or sea-shells. They dwell in habitations constructed of wood, bamboos, and straw; and there is only an inconsiderable difference between those of the more wealthy and the poorer classes. With regard to their state of civilization, or their manners and customs, we have very little certain information applicable to the present times. Most probably the mountaineers are more barbarous than the inhabitants of the low country and the plains; and as the kingdom is divided into a number of

petty states, those may be subordinate to some paramount authority; but the frequent broils of the rajahs retard the civilization of their subjects. Mahommed Cazim, who entertained a decided aversion to the Assamese, reproaches them with indiscriminately feeding "on all kinds of food, human flesh excepted; they even eat animals that have died a natural death." He divides them into two tribes, Assamians and Cultanians; the latter excelling the former in every thing but warlike operations.

It appears that the government of this kingdom is monarchical, and that a sultan or rajah rules the whole; yet, owing to the incessant contest for power, the course of succession, if it be hereditary, is disturbed, and the most potent chief, gaining an ascendancy, restores the country to peace. The government was wont to be mildly administered: in the words of Turpin, the "king was attentive to the happiness of his subjects, and employed none excepting slaves to labour in the mines. It was the only country where humanity was not crushed under the pressure of despotism." Formerly the rajah kept a guard of six or seven thousand warlike troops, whose courage was equal to any enterprise.

The religion of these people is supposed by Mr Hamilton to be Brahminical. It is certain that they have many temples erected to their divinities throughout their territories, although the character and description of these divinities have never been explained. In the time of Aurungzebe they are said to have had no settled faith: They do not adopt any mode of worship practised either by Heathens or Mahometans; nor do they concur with any of the known sects which prevail amongst mankind. But it is by no means credible that all their temples have been erected since that era. Rafts covered with human heads are sometimes seen floating down the Brahmaputra through Bengal, which has excited conjectures that they belonged to victims offered to their sanguinary deities. It is not evident, however, that human sacrifices, unless the destruction of life at funeral obsequies be called such, are publicly offered up in the neighbouring Asiatic territories. This species of barbarity has been widely extended over the world; captives were slaughtered at the pile of the ancients,—slaves were buried alive to serve their masters in the world to come,—and even the chosen wife of her husband's affections has been doomed to destruction at the same moment that his earthly remains were consigned to oblivion. Such customs have been familiar to mankind from the earliest records of time, and, among the rest, were practised by the natives of Assam. On the decease of a rajah, or any distinguished person, a capacious pit was prepared, where not only his own body, but many of his women and attendants, were also buried. Of the latter was a torch-bearer, together with a quantity of oil and lamps, as essential to his comfort in a future state; some of his most elegant and useful furniture, carpets and clothes, were, in like manner, included; and even elephants, together with gold and silver, formed part of the promiscuous assemblage. A strong roof, resting on thick timbers, was then constructed over the pit, and the miserable victims not already slain were left to perish by a lingering death.

In regard to the state of the arts, it is to be inferred that the Assamese are behind many nations in their vicinity. Formerly they manufactured excellent silks, chiefly for home consumption; they likewise fabricated velvet, and embroidered it beautifully with flowers. Perhaps the same is continued, as also the extraction of salt from vegetable substances; and their gunpowder was reputed of the best quality. Nay, the easterns hence ascribed the invention of this destructive substance to their ingenuity, and affirm that it passed from them to Pegu, and

thence to China. Their chief exports to Bengal are gold, elephants' teeth, two kinds of lac, which was esteemed the finest in those regions, a coarse raw silk, and coarse cotton cloths. Brandy is made from grapes, afforded by the numerous vines in Assam. Agriculture is certainly well understood: the populousness of several districts which have attracted the attention of the traveller, proves that there is no scarcity of subsistence; and well-frequented fairs are spoken of as being held in different places. Assam contains some celebrated temples, probably of ancient date; and their military causeways, constructed at an early period of their history, are of admirable extent and magnitude. One of these, now in a state of decay, runs from Cooch Bahar in Bengal, through Rangamatty, to the utmost extremity of the eastern limits of the kingdom, serving as a boundary of the Bootan dominions. Another, a work of immense labour, passes the capital; and the banks of the Dhekow are connected with the southern mountains by a lofty rampart, traversing the space of ten or fifteen miles. It is undoubted, that although most authors who have treated of this subject describe these structures as military causeways only, they have served both as the means of communication among the inhabitants during the season of inundations, and as barriers to the overflowing rivers spreading still farther on the plains. Thus the great causeway which approaches the capital was raised to preserve the interior from the inundations of the Dehingh, while in the dry season the river retires two miles from its base.

A great many towns and villages are scattered over the banks of the rivers of Assam, these having been peculiarly selected by the natives for their habitations; and a certain number seems to be included in a circle under the same administration. The capital, which is called Ghergong, Kirgana, or perhaps more properly Gurgown, is situated in 25° 35' north latitude, 93° 10' east longitude, at a considerable distance above Rungpore, which is sometimes called the capital, but is only the military station of Ghergong. It stands on the high banks of the river Dhekow or Degoo. This city Dr Wade, who resided ten years in Assam, describes to have been ten miles long by five in breadth; and we learn from other authors that it was fortified and encircled by a fence of bamboos, inclosing villages and fields in its circuit. Like other cities of the East, each house stood separate, amidst a cultivated spot or garden; each side of the river was lined with dwellings, and the royal palace was situated on its banks. It had four gates, constructed of earth and stone, from each of which the palace was distant four miles and a half, by which means its position was nearly in the centre, and close to the Dhekow. This palace was a spacious edifice, apparently between two and three miles in circuit, surrounded by a causeway, planted on each side by a close bamboo hedge, serving instead of a wall, and beyond them a wet ditch, always full of water. The interior contained many apartments, both for state and convenience, elegantly ornamented. Mahommed affirms it as an undoubted fact, that 3000 carpenters and 12,000 labourers were constantly occupied, during two years, in constructing the palace; but an insurrection, which took place about the year 1790, proved almost totally destructive of it and the rest of the city. Rungpore, situated in 25° 47' north latitude, and 89° 5' east longitude, stands on the opposite side of the Dhekow, with the river Numdaugh flowing on the south; a rampart or causeway to resist the inundations protects it on the east; and on the west it is secured by a bridge, the only access whereby it can be approached. The circle including it contains several towns, and is about twelve miles in length by ten in breadth. Goahauttee is the capital of Lower Assam, and

Assam.

the residence of a viceroy. The surrounding territory occupies a hilly country on both sides of the Brahmaputra, the hills on each side forming a spacious amphitheatre, which has been fortified equally by nature and art. The district Goahatee is divided into north and south, including several strong passes among the fortified hills. A great number of other towns might be mentioned by name; but, excepting their position, we are unacquainted with any thing regarding them.

The history of this kingdom is involved in great obscurity, arising both from its remote situation, and from a jealousy of strangers, which has almost entirely precluded the access of Europeans; and by a singular fatality, after this difficulty had been conquered by the admission and residence of an intelligent physician, Dr Wade, some of the most important materials collected by him were lost on being transmitted to Europe. The present race of inhabitants is said to have occupied the country during a thousand years, but not by any means in tranquillity; at least we know that, since 1638, they have been involved in frequent contests with their neighbours. In these, however, they have in general been successful, for unconquerable obstacles are opposed to their enemies. "Whenever an invading army has entered their territories, the Assamese have sheltered themselves in strong posts, and have distressed the enemy by stratagems, surprises, and alarms, and by cutting off their provisions. If these means failed, they have declined a battle in the field, but have carried the peasants into the mountains, burnt the grain, and left the country desert. But when the rainy season has set in upon the advancing enemy, they have watched their opportunity to make excursions and vent their rage; the famished invaders have either become their prisoners, or been put to death. In this manner powerful and numerous armies have been sunk in that whirlpool of destruction, and not a soul has escaped." Such dangers were sufficient to intimidate the boldest adventurers, and we have the testimony of eye-witnesses that they are not exaggerated. About the close of the fifteenth century, Husein Shah, king of Bengal, invaded Assam with a formidable force of cavalry, infantry, and also of boats; and, in the outset, was successful. The rajah, unable to meet him in the plains, retired to the mountains, whither Husein could not follow him; but returning to Bengal, he left his son with a large army to keep possession of the country; the rainy season commenced, and the roads were shut up by inundations; then the rajah descended from the mountains, intercepted the supplies of the invaders, harassed them with skirmishes, and cut off the whole in detail. Another prince of Hindostan attempted the conquest of Assam, with an immense force of cavalry; but, says the author who records the enterprise, they were all devoted to oblivion in that country of enchantment, and no intelligence or vestige of them remained. The Assamese, however, in 1638 met with a reverse of fortune in leaving their own confines to sail down the Brahmaputra and assail the inhabitants of Bengal, being repulsed by the troops of Shah Jahan.

The rajah of Assam had assumed or preserved the title of Sarjee or Swerg, which signifies celestial, and lived in great pomp and splendour in the reign of Aurungzebe, the Mogul emperor, who died in 1707. That great prince, desirous of extending his conquests, sent an army, under an able general, to attempt the subjugation of this kingdom; partly, it would appear, to humble the pride of the rajah, who was so vain-glorious as to believe that his ancestors were of divine origin, and that one of them, inclining to visit the earth, descended by a golden ladder; and partly to disseminate the principles of the Mahometan faith. The army advanced victoriously, conquering all

opposition, and gained possession of the capital. There the imperial general, considering himself firmly established, made many regulations for internal administration, and also proclaimed the Mahometan religion. Measures were taken for keeping the roads open, and for supplying the army with provisions; and, as the season was now changing, he resolved, when the inundations subsided, to put his troops in motion to extirpate the rajah and those adherents who had escaped. The conquest of Assam extended to a large portion of the country, for all the villages of Decancole submitted to the invaders, and those of Ootrecole followed; yet it is not to be inferred that this was accomplished without loss; for the panegyrist of the general describes the country as spacious, populous, and hard to be penetrated; that it abounded in dangers; that the paths and roads were beset with difficulties; and that the obstacles to conquest were more than could be expressed. The inhabitants, he says, were enterprising, well armed, and always prepared for battle. They had lofty forts, numerous garrisons and plentifully provided with warlike stores; and the approach to them was opposed by thick and dangerous jungles and broad and boisterous rivers. Under these circumstances it was wonderful that the army prevailed; "but the Mussulman hordes experienced the comfort of fighting for their religion, and the blessings of it reverted to the sovereignty of his just and pious Majesty." But the Assamese were unsubdued: the climate proved destructive to the Moguls, who were obliged to evacuate the city, and, after being harassed by the natives, to retreat from the country with diminished numbers.

Towards the earlier part of the eighteenth century, it is said that some of the Brahmins of Bengal reached Assam, desirous of introducing their religion there, where the inhabitants still had no settled faith. Amidst their exertions for this great object, they persuaded them that it would be gratifying to their deity, Brahma, if they would use salt imported from Bengal in preference to their own, which it greatly excelled. To this the sovereign consented, on condition that it should be monopolized by himself, and that the vessels conveying it should not penetrate beyond the frontier; and, in consequence, forty vessels, each of from 500 to 600 tons burden, have annually been sent thither.

About the year 1790, the kingdom was in the most distracted state from a widely extended insurrection, followed by the absolute destruction of many important places; and, in the year 1793, a detachment of British troops was sent to aid the restoration of the rajah, who seems to have been dethroned by the insurgents. This detachment gained the capital, and completely effected their object; and the rajah was so sensible of the assistance he had received, that he immediately concluded a commercial treaty very favourable to the British interests. It was probably on this occasion that Dr Wade visited Assam, and that Mr Wood, of the engineers, constructed a map of a considerable portion of the country. Either this or another was transmitted to Britain, we have understood, to be deposited in the Advocates' Library at Edinburgh; but, after its arrival, it unfortunately never reached the place of its destination, which is much to be regretted, since the geography and history of the country are both so little known.

ASSARIUM, in *Antiquity*, denotes a small copper coin, being a part or diminutive of the *as*. The word *ασσαριον* is used by Suidas indifferently with *οβολος* and *νομισμα*, to denote a small piece of money; in which he is followed by Cujacius, who defines *ασσαριον* by *minimus aeris nummus*. We find mention of the assarium in the gospel of St Matthew, chap. x. ver. 29.

Assam
Assarium.

ASSARO, a city in the island of Sicily, and intendency of Calatanissetta, containing 3300 inhabitants. The situation is lofty and healthy, but there is nothing remarkable except a number of caverns in the hills in its neighbourhood.

ASSARON, or OMER, a measure of capacity in use among the Hebrews, containing five pints. It was the measure of manna which God appointed for every Israelite.

ASSASSIN, a person who kills another with the advantage either of an inequality in the weapons, or by means of the situation of the place, or by attacking him at unawares. The word *assassin* is said by some to have been introduced from the Levant, where it took its rise from a certain prince of the family of the *Arsacidae*, popularly called *Assassins*, living in a castle between Antioch and Damascus, and bringing up a number of young men, ready to pay a blind obedience to his commands; whom he employed in murdering the princes with whom he was at enmity. But according to Mr Volney, the word *Hassassin* (from the root *hass*, to kill, to assassinate, to listen, to surprise), in the vulgar Arabic, signifies *robbers of the night*, persons who *lie in ambush to kill*; and is universally understood in this sense at Cairo and at Syria. Hence it was applied to the *Batenians*, a tribe of Syria, who slew by surprise. This people probably owed their origin to the Carmatians, a famous heretical sect among the Mahometans, who settled in Persia about the year 1090; whence, in process of time, they sent a colony into Syria, where they became possessed of a considerable tract of land among the mountains of Lebanon, extending itself from the neighbourhood of Antioch to Damascus. The first chief and legislator of this remarkable tribe appears to have been Hassan Ben Sabah, a subtle impostor, who by his artifices made fanatical and implicit slaves of his subjects. Their religion was compounded of that of the Magi, the Jews, the Christians, and the Mahometans; but the capital article of their creed was to believe that the Holy Ghost resided in their chief; that his orders proceeded from God himself, and were real declarations of his divine pleasure. To this monarch the orientals gave the name of *Sheikh-el-Jebelz*; but he is better known in Europe by the name of the *Old Man of the Mountain*. This chief, from his residence on Mount Lebanon, like a vindictive deity, with the thunderbolt in his hand, sent inevitable death to all quarters of the world; so that from one end of the earth to the other, caliphs, emperors, sultans, kings, princes, Christians, Mahometans, and Jews, every nation and people, execrated and dreaded his sanguinary power, from the strokes of which there was no security. At the least suggestion or whisper that he had threatened the death of any potentate, all immediately doubled their guards, and took every other precaution in their power. It is known that Philip Augustus, king of France, on a premature advice that the sheikh intended to have him assassinated, instituted a new body-guard of men distinguished for their activity and courage, called *sergens d'armes*, with brass clubs, and bows and arrows; and he himself never appeared without a club, fortified either with iron or gold. Most sovereigns paid secretly a pension to the sheikh, however scandalous and derogatory it might be to the lustre of majesty, for the safety of their persons. The knights-templars alone dared to defy his secret machinations and open force. This people once had, or at least they feigned to have, an intention of embracing the Christian religion. They reigned a long time in Persia and on Mount Lebanon. Holagoo or Hulaku, a leader of the Mogul Tartars, in the year 655 of the Hegira, or 1254 of the Christian era, entered their country and dispossessed them of several places; but it was not till some years after that they were totally ex-

tirpated. This achievement was owing to the conduct and intrepidity of the Egyptian forces sent against them by the Sultan Bibars.

A *History of the Assassins*, in the German language, by Mr Von Hammer, was published at Stuttgard in 1818. It contains some new and striking views of the origin, proceedings, and doctrines of the sect. He represents them as forming a military and religious order, subject to the control and direction of a grand master, like the templars, to whom the title of Old Man of the Mountain was applied. We must content ourselves with referring our readers to this learned and curious work.

ASSAULT, in *English Law*, is an offer or attempt to hurt the person of another; as, if one lifts up his cane or his fist in a threatening manner at another, or strikes at him, but misses him, this is an assault; the actual touching of the person not being necessary to make the offence. Finch describes it to be "an unlawful setting upon one's person." No words whatsoever, be they ever so provoking, can amount to an assault. There are, however, opinions to the contrary.

ASSAY, ESSAY, or SAY, in *Metallurgy*, the proof or trial of the goodness, purity, value, &c. of metals and metalline substances. In ancient statutes this is called *touch*, and those who had the care of it *keepers of the touch*.

ASSAYING, taken generally, implies an examination or analysis of any ore or substance whose constituent parts are to be chemically determined. The term, however, more particularly relates to the ascertaining of the qualities of gold and silver in relation to their state of purity; and in the following observations we mean to confine ourselves entirely to this object.

In whatever point of view we consider the art of assay-Importing-
ing these metals, it cannot fail to appear of great importance to the welfare and prosperity of the civilized world, this art.
Every one must be aware of the importance of a metallic currency agreeing in its standard fineness with the decree which establishes its circulation, and that it is an object of the greatest consequence to a nation to have the means of ascertaining with accuracy the value of the coins issued by the authority of the monarch. Since the reign of Henry VIII. we have had no capricious and unjustifiable changes in the standard fineness of our coins. That monarch, as Dr Henry remarks, "after he had squandered all his father's treasures, the grants he had received from parliament, and the great sums he had derived from the dissolution of the religious houses, began to diminish his coins both in weight and fineness. This diminution at first was small, in hopes, perhaps, that it would not be perceived: but after he had got into this fatal career, he proceeded by rapid steps to the most pernicious lengths. In the 36th year of his reign silver money of all the different kinds was coined, which had only one half silver and the other half alloy. He did not even stop here: in the last year of his reign he coined money that had only 4 oz. of silver and 8 oz. of alloy in the pound weight; and the nominal pound of this base money was worth only 9s. 3½d. of our present money. He began to debase his gold coins at the same time, and proceeded by the same degrees. But it would be tedious to follow him in every step. In this degraded and debased condition Henry VIII. left the money of his kingdom to his son and successor Edward VI. This shameful debasement of the money of his kingdom was one of the most imprudent, dishonourable, and pernicious measures of his reign: it was productive of innumerable inconveniences and great perplexity in business of all kinds, and the restoration of it to its standard purity was found to be a work of great difficulty." (Henry's *History of Great Britain*, vol. xii. p. 336 and 337.)

Assault
||
Assaying.

Assaying.

To possess the art, therefore, by which such dishonourable proceedings as are just detailed may be speedily detected, is evidently an object of the greatest utility; inasmuch as the debasement of the coin would require an adjustment of the relative value of commodities to the degraded standard; and the more facility that can be given to this adjustment, the less perplexity and injury will be sustained by the public.

The importance of the art of assaying will further appear when we consider the extent of the manufacture of plate, and ornamental articles of gold and silver, the standard value of which is determined by an assay of a few Troy grains only. The nicety and delicacy of the operation must be great, and much practical experience requisite, to obtain uniformly a satisfactory result.

Description of implements.

The principle of assaying gold and silver is very simple: It consists of two operations—the separation of the alloy from the precious metals, and the parting of these latter from each other.

Before proceeding to the detailed description of these processes, we shall describe the furnaces and implements used in the art of assaying.

Plate LXXVIII. AAAA, fig. 1, is a front elevation of an assay furnace; *aa* a view of one of the two iron rollers on which the furnace rests, and by means of which it is moved forward or backward; *b* the ash-pit; *cc* are the ash-pit dampers, which are moved in a horizontal direction towards each other for regulating the draught of the furnace; *d* the door or opening by which the cupels and assays are introduced into the muffle; *e* a movable funnel or chimney, by which the draught of the furnace is increased.

BBBB, fig. 2, is a perpendicular section of fig. 1; *aa* end view of the rollers; *b* the ash-pit; *c* one of the ash-pit dampers; *d* the grate; *e* the plate upon which the muffle rests, and which is covered with loam nearly one inch thick; *f* the muffle in section representing the situation of the cupels; *g* the mouth-plate, and upon it are laid pieces of charcoal, which during the process are ignited, and heat the air that is allowed to pass over the cupels, and which will be more fully explained in the sequel; *h* the interior of the furnace, exhibiting the fuel.

The total height of the furnace is 2 feet 6½ inches; from the bottom to the grate, 6 inches; the grate, muffle, plate, and bed of loam with which it is covered, 3 inches; from the upper surface of the grate to the commencement of the funnel, *e* fig. 1, 21½ inches; the funnel *e* 6 inches. The square of the furnace which receives the muffle and fuel is 11¾ inches by 15 inches. The external sides of the furnace are made of plates of wrought iron, and are lined with a 2-inch fire-brick.

CCCC, fig. 3, is a horizontal section of the furnace over the grate, showing the width of the mouth-piece or plate of wrought iron, which is 6 inches, and the opening which receives the muffle-plate.

Fig. 4 represents the muffle or pot, which is 12 inches long, 6 inches broad inside; in the clear 6¾: in height 4½ inside measure, and nearly 5½ in the clear.

Fig. 5, the muffle-plate, and which is of the same size as the bottom of the muffle.

Fig. 6 is a representation of the sliding door of the mouth-plate, as shown at *d* in fig. 1.

Fig. 7, a front view of the mouth-plate or piece, *d* fig. 1.

Fig. 8, a representation of the mode of making, or shutting up with pieces of charcoal, the mouth of the furnace.

Fig. 9, a view of the cupel, which is generally one inch by ¾ths of an inch.

Fig. 10, the teaser for cleaning the grate.

Fig. 11, a larger teaser, which is introduced at the top of the furnace, for keeping a complete supply of charcoal around the muffle.

Fig. 12, the tongs used for charging the assays into the cupels.

Fig. 13 represents a board of wood used as a register, and is divided into 45 equal compartments, upon which the assays are placed previous to their being introduced into the furnace. When the operation is performed, the cupels are placed in the furnace in situations corresponding to these assays on the board. By these means all confusion is avoided, and without this regularity it would be impossible to preserve the accuracy which the delicate operations of the assayer require.

The furnace and implements which we have just detailed are such as are used in the Royal Mint and Goldsmiths' Hall in the city of London.

We shall now proceed to a description of a small assay furnace invented by Messrs Anfrye and D'Arcet of Paris. They term it *Le Petit Fourneau à Coupelle*. Fig. 14 represents this furnace, and it is composed of a chimney or pipe of wrought iron *a*, and of the furnace *B*. It is 17½ inches high and 7½ inches wide. The furnace is formed of three pieces; of a dome *A*; the body of the furnace *B*; and the ash-pit *C*, which is used as the base of the furnace, fig. 14 and 15. The principal piece or body of the furnace *B* has the form of a hollow tower, or of a hollow cylinder, flattened equally at the two opposite sides, parallel to the axis, in such a manner that the horizontal section is elliptical. The foot which supports it is a hollow truncated cone, flattened in like manner upon the two opposite sides, and having consequently for its basis two ellipses of different diameters; the smallest ought to be equal to that of the furnace, so that the bottom of the latter may exactly fit it. The dome, which forms an arch above the furnace, has also its base elliptical, whilst that of the superior orifice by which the smoke goes out preserves the cylindrical form. The tube of wrought iron is 18 inches long and 2½ inches diameter, having one of its ends a little enlarged and slightly conical, that it may be exactly fitted or jointed upon the upper part of the furnace dome *d*, fig. 14. At the union of the conical and cylindrical parts of the tube there is placed a small gallery of iron *e*, fig. 14, 15, and 16. See also the plan of it, fig. 17. This gallery is both ingenious, useful, and necessary. Upon it are placed the cupels, which are properly heated during the ordinary work of the furnace, that they may be introduced into the muffle when it is brought into its proper degree of heat. A little above this gallery is a door *f*, by which, if thought proper, the charcoal could be introduced into the furnace; and above that there is placed at *g* a key or valve, which is used for regulating the draught of the furnace at pleasure. Messrs Anfrye and D'Arcet say, that, to give the furnace the necessary degree of heat so as to work the assays of gold, the tube must be about 18 inches high above the gallery for annealing or heating the cupels. The circular opening *h*, in the dome, fig. 14, and as seen in the section, fig. 15, is used to introduce the charcoal into the furnace: it is also used to inspect the interior of the furnace, and to arrange the charcoal round the muffle. This opening is kept shut during the working of the furnace, with the mouth-piece, of which the face is seen at *n*, fig. 15.

The section of the furnace, fig. 15, presents several openings: the principal, which is that of the muffle, is placed in *i*; it is shut with the semicircular door *m*, fig. 14, and as seen in the section *m*, fig. 15. In front of this opening is the table or shelf upon which the door of the muffle is made to advance or recede; the letter *q*, fig. 15, shows the face, side, and cross section of the shelf, which makes part of the furnace. Immediately under the shelf is a horizontal slit *l*, which is pierced at the level of the upper part of the grate, and used for the introduction of

the rod of iron, fig. 31, that the grate may be easily kept clean. This opening is shut at pleasure by the wedge represented at *k*, fig. 14 and 15.

Upon the back of the furnace is a horizontal slit *p*, fig. 15, which supports the fire-brick *S*, fig. 15, and upon which the end of the muffle, if necessary, may rest: *u*, fig. 15, is the opening in the furnace where the muffle is placed.

Fig. 19 is a plan of the grate of the furnace, and fig. 20 a horizontal view of it. These two figures show us the dimensions of the ellipses, and determine the general form of the furnace, and thickness of the grate. To give strength and solidity to the grate, it is encircled by a bar or hoop of iron. We see at *z* the groove in which the hoop of iron is fixed. The holes of the grate are truncated cones, having the greatest base below, that the ashes may more easily fall into the ash-pit. The letter *v*, fig. 15, shows the form of these holes. The grate is supported by a small bank or shelf, making part of the furnace, as seen at *a*, fig. 15.

The ash-pit *C* has an opening *y* in front, fig. 15, and is shut when necessary by the mouth-piece *r*, fig. 14 and 15.

To give strength and solidity to the furnace, it is bound with hoops of iron at *b*, *b*, *b*, *b*, fig. 14.

Figs. 21, 22, and 23, are views of the muffle.

Fig. 24 is a view of a crucible for annealing gold.

Figs. 25, 26, and 27, are cupels of various sizes to be used in the furnace. They are the same as those used by assayers in their ordinary furnaces.

Figs. 28 and 29 are views of the hand-shovels used for filling the furnace with charcoal; they should be made of such size and form as to fit the opening *h* in figs. 14 and 15.

Fig. 30, the smaller pincers or tongs by which the assays are charged into the cupels, and by which the latter are withdrawn from the furnace.

Fig. 18, the teaser for cleaning the grate of the furnace.

Fig. 16 is a representation of the furnace first constructed by Messrs Anfrye and d'Arcet, and which was worked by means of a pair of bellows, which forced a current of air through the brass tube *b*, entering the ash-pit under the grate at the circular hole *c*, fig. 15. The strength of the blast or current of air can be regulated at pleasure by the stop-cock *d*, fig. 16.

We shall now proceed to a description of the process of assaying, as performed by the assayers of the Royal Mint and Goldsmiths' Hall, and shall then state the facility afforded by the furnace of Messrs Anfrye and d'Arcet in conducting this operation upon a smaller scale and reduced expense.

Some preliminary observations may be requisite in regard to the muffle and cupels, to the proportioning of lead in assaying, &c. before the operation of the assay commences.

In the furnace above described, the number of assays that can be made at one time is 45. The same number of cupels are put into the muffle. The furnace is then filled with charcoal to the top, and upon this are laid a few pieces already ignited. In the course of three hours, a little more or less, according to circumstances, the whole is ignited, during which period the muffle, which is made of fire-clay, is gradually heated to redness, and is prevented from cracking, which a less regular or more sudden increase of temperature would not fail to do: the cupels also become properly annealed. All moisture being dispelled, they are in a fit state to receive the piece of silver or gold to be assayed.

The greater care that is exercised in this operation, the less liable is the assayer to accidents from the breaking of the muffle, which it is both expensive and troublesome to fit properly into the furnace.

The cupels used in the assay process are made of the ashes of burnt bones (phosphate of lime). In the Royal Mint the cores of oxhorn are selected for this purpose, and the ashes produced are about four times the expense of the bone-ash used in the process of cupellation upon the large scale. So much depends upon the accuracy of an assay of gold or silver, where a mass of 15 lbs. Troy in the first and 60 lbs. Troy in the second instance is determined by the analysis of a portion not exceeding 20 Troy grains, that every precaution which the longest experience has suggested is used to obtain an accurate result: hence the attention paid to the selection of the most proper materials for making the cupels.

The cupels are formed in a circular mould made of cast steel, very nicely turned, and by which means they are easily freed from the mould when struck. The bone-ash is used moistened with a quantity of water sufficient to make the particles adhere firmly together. The circular mould is filled and pressed level with its surface, after which a pestle or rammer, having its end nicely turned, of a globular or convex shape, and its size equal to the degree of concavity wished to be made in the cupel for the reception of the assay, is placed upon the ashes in the mould, and struck with a hammer until the cupel is properly formed. These cupels are allowed to dry in the air for some time before they are used. If the weather is dry, a fortnight will be sufficient.

The greatest possible attention should be paid to the quality of the lead used in assaying. If it contain silver, it will be easy to perceive a source of material error in the delicate operations of the assayer. Lead revived from litharge contains only about half a grain in the pound weight, and is preferred on that account to lead immediately revived from the ore, which usually contains a larger quantity.

The proportion of lead used in an assay of silver varies according as the external character of the silver to be assayed indicates a comparative state of fineness or coarseness to standard metal; which an expert assayer may pretty accurately determine by the eye: but his opinion will also in some measure be regulated by the comparative ease or difficulty of flattening upon an anvil the piece of silver to be assayed;—if coarse, the metal is harder than standard, and of a brilliant glossy appearance; but if soft and easily flattened, and of a dead white colour, it will indicate a state approaching to purity. The quantity of lead is then proportioned by the opinion of the assayer, and varies from 10 to 20 times the weight of the silver used. It should be observed, that a cupel is capable of absorbing only its own weight of litharge; and attention should accordingly be paid to the size of the cupel, when any silver is to be assayed which requires a great quantity of lead.

As it is always requisite to proportion the lead to the estimated quantity of alloy in the silver before cupellation, the ancient assayers made use of *touch-needles*, which were bars or slips of metal made with pure silver, alloyed with definite proportions of copper in a regularly increasing series, from the least to the greatest proportion which may ever be required. The silver to be assayed was examined in comparison with the touch-needles in colour, tenacity, and other external characters; and its alloy was estimated by that of the needle to which it showed the closest resemblance. These needles are seldom or never used now; and the external character of the metal is sufficient to guide an experienced assayer in the proportioning of the lead to the estimated alloy in the silver which he has to assay.

In Aikin's *Dictionary of Chemistry and Mineralogy*, under the article *ASSAYING*, there is a table of the pro-

Assaying. portions of lead to the estimated alloy in fine silver, founded upon the experiments of Messrs Tillet, Hellot, and Macquer, which were the basis of a regulation subsequently adopted by an edict of the late French government. The great uncertainty of the use of the touch-needles probably suggested these experiments to the French chemists; and as this table may be extremely useful to inexperienced assayers, we shall insert it here, together with the observations accompanying it in the above work.

"Copper, the usual alloy of the fine metals, when taken singly, is found to require from ten to fourteen times its weight of lead for complete scorification on the cupel. Now, all admixtures of fine metal tend to protect the copper from the action of the litharge, and the more obstinately, the greater the proportion of fine metal; so that

Assaying. copper with three times its weight of silver (or 9 oz. fine), requires forty times as much lead as copper; with eleven parts of silver it requires seventy-two parts of lead, and the like in an increasing ratio. The following is the table of the proportions of lead required to different alloys of copper, of which a few points are founded on the above-mentioned experiments, and the rest filled up according to the estimated ratio of increase (being multiples of the assay integer 24 in arithmetical progression). In the three first columns is shown the absolute increase of the quantity of lead in alloys of decreasing fineness; in the three last columns will be seen the gradual diminution of the protecting power of fine metal against scorification in proportion to the increase of alloy, shown by the decreasing quantity of lead required for the same weight of copper under different mixtures."

TABLE.

Silver.	Copper.	Lead.	Ratio of Increase.			Copper.	Silver.	Lead.
23 with	1 requires	96	= 4 × 24	and hence	1 with	23 requires	96	
22 ...	2	144	= 6 × 24		1 ...	11	72	
20 ...	4	192	= 8 × 24		1 ...	5	48	
18 ...	6	240	= 10 × 24		1 ...	3	40	
16 ...	8	288	= 12 × 24		1 ...	2	36	
14 ...	10	336	= 14 × 24		1 ...	1½	33	
12 ...	12	384	= 16 × 24		1 ...	1	32	
10 ...	14	432	= 18 × 24		1 ...	5⁄4	30	
8 ...	16	480	= 20 × 24		1 ...	1½	30	
6 ...	18	528	= 22 × 24		1 ...	1⅓	29 ×	
4 ...	20	576	= 24 × 24		1 ...	1¼	28 ×	
2 ...	22	624	= 26 × 24		1 ...	1⅑	28 ×	

In the article just referred to, it is remarked that many assayers of good authority use proportions of lead to alloy considerably different from the above table, and that the whole of the numbers here given may be considered as rather high in regard to the quantity of lead. The German assayers, it is added, observe the following rule:

Copper.	Silver.	Lead.
1 with	30 requires	128
1	15	96
1	7	64
1	4	56
1	3	40
1	1	30
1	$\frac{1}{2}$	20
1	$\frac{1}{3}$	17

In proportioning the lead to the alloy supposed to exist in the silver to be assayed, care must be taken not unnecessarily to increase the quantity; though it would be all oxidated or absorbed by the cupel sooner or later; which is proved by the cupellation of lead *per se*, in order to ascertain the portion of silver it contains; the latter being always found in a globular shape on the cupel and in a state of purity.

In the process of cupellation with lead, however, there is always a loss of silver. Mr Tillet found, by experiments which he made with pure silver and lead, whose retent of silver was known, that after the process of cupellation, the button of silver was never precisely of the same weight as before, but was always a portion lighter, even when the heat of the assay furnace was not sufficient to drive off any of the silver. The conclusion was obvious,—a part of the silver was carried into the cupel by the lead. This was proved by reviving the oxide of lead from the cupel, and cupelling the lead by itself, when the quantity of silver left upon the test was found to be ten

times as great as the natural proportion of this metal in the lead, and very nearly corresponded with the loss of silver in the first instance. It will be obvious, then, that the assayer's report of the title or purity of any sample of silver, unless corrected, would make the metal somewhat less pure than it actually is, because all loss is put to the account of alloy. Mr Tillet calculates, when no more lead is used than is necessary for the entire separation of the alloy, that it carries down into the cupel as much silver as, when the whole is again reduced, would make the noble metal $\frac{1}{28}$ of the mass, when the natural admixture of the silver is only about $\frac{1}{1132}$. But if an excess of lead is employed for cupellation, this loss of silver is somewhat greater, though it does not increase in the ratio of the excess of the lead; for 10 parts of lead to a given alloy will not carry down twice as much silver as 5 parts, though the difference of loss will be very sensible.

The weights used in assaying gold and silver are peculiar to the profession. In the assaying of silver a given number of grains are taken, which is called the *assay pound*. This assay pound varies from 14 to 24 grains Troy. This imaginary pound is subdivided into ounces and pennyweights, and the latter into half-pennyweights, which is the lowest term used in reporting assays of silver; so that there are 480 different reports for silver (this being the number of half-pennyweights in the pound); and therefore each nominal half-pennyweight weighs $\frac{1}{20}$ of a Troy grain when the entire assay pound is 24 grains.

The report of an assay of silver is made according to the proportion of pure metal which it is found to contain. The legal standard of Sterling money of silver is 11 oz. and 2 dwts. fine, and 18 dwts. alloy. If an assay of silver was found to contain 11 oz. only of pure silver, it would be reported *worse* 2 dwts., meaning worse than standard silver by 2 dwts. or 48 grains in the pound Troy. If an

Assaying. assay, on the contrary, contained 11 oz. and 6 dwts. pure silver, it would be reported *better* than standard by 4 dwts. in the pound Troy; because 18 dwts. being the standard proportion of alloy, it was found that it only contained 14 dwts. alloy. When bullion thus assayed and reported is for sale, its value is calculated by reducing the bar or ingot of silver into standard metal.

In the first example which we have given, lbs. Troy. oz.
if the ingot of silver assayed weighed..... 50 0
there would be deducted from the weight 2
dwts. per lb. or..... 0 5
which 5 oz. is the excess of alloy above the
proportion of 18 dwts. to the 11 oz. 2 dwts.
of fine metal, and the bar of silver would be,
in standard weight,..... 49 7

On the contrary, if the ingot weighed.....
and the alloy were deficient, which is the
case when the metal is reported better than
standard by 4 dwts. in the pound Troy, there
would be added to the 50 lbs. 4 dwts. per
pound, which would be equal to..... 0 10

Making the standard weight of the ingot.... 50 10

The gold assay pound, which is from 10 to 20 grains Troy, is subdivided into 24 carats, and each carat into 4 assay grains, and each grain into quarters; so that there are 384 separate reports for gold, each equal to 15 Troy grains, or what is termed a quarter carat grain. An accurate assayer, however, can ascertain, in an assay of gold, to 3 grains Troy; but it is the custom of the trade not to report less than a quarter carat, or 15 grains Troy. A substantial reason is given for this rule to justify the practice of it. An ingot of gold generally weighs a journey weight, which is 15 lbs. Troy; from a sample cut from the two opposite ends, weighing from 10 to 20 grains, the value of the mass of 15 lbs. is to be determined: if this ingot had been imperfectly melted, the mass would not be homogeneous, and a difference might exist in it of several Troy grains; and the allowance between the quarters given in the assay report is an indemnity to the purchaser. Indeed, so particular are many in the bullion trade, that they will not purchase any foreign gold bullion until it has been remelted by refiners or melters in whose integrity they repose confidence. This, we believe, is generally the case with the Bank of England in all her purchases of foreign gold bullion.

The assay report of gold is made according as it is better or worse than standard. The standard of our gold coin is 22 carats fine and 2 carats alloy. If, by assay, an ingot of gold was found to contain 21 carats fine gold, it would be reported *worse* 1 carat, the mass containing a carat of alloy more than the proportion of 2 carats to 22 carats fine. If the ingot weighed 15 lbs. Troy, there would be deducted from the gross weight 1 carat, or 240 grains Troy, reducing the standard of the mass to 14 lbs. 11 oz. 10 dwts. If, on the contrary, the mass was found to contain 23 carats fine gold, it would be reported 1 carat *better* than standard; and this carat would be added to the gross weight of the ingot, which we have supposed to weigh 15 lbs. Troy, and would be called 15 lbs. 0 oz. 10 dwts. of standard gold. When the gold assay pound or integer is only 12 grains, the quarter assay grain weighs only $\frac{1}{4}$ part of a Troy grain. This will show how delicate the scales must be by which the assayer works in order to obtain accuracy. In the Royal Mint the scales of the assayers will be sensibly affected even with the $\frac{1}{1000}$ th part of a Troy grain.

When the assay pound is subdivided, as for silver, in the same manner as the Troy pound, it is obvious that all the lower denominations bear the same relation to each other, which is some little advantage in transferring the assay reports to real mixtures for use. On the contrary, the carat subdivision for gold is confined to assaying; but its fractions being aliquot parts of the pound Troy, the calculation for real use is very easy. As the pound Troy contains 5760 grains, the carat corresponds with 240 grains or 10 dwts.; the assay grain, or fourth part of a carat, with 60 Troy grains; and the assay quarter-grain with 15 Troy grains; to which report, when the assayer has separated the gold (4 oz. for example), he adds 4 oz. *gold in a pound Troy*. Whereas in gold-parting he takes two equal pieces, treats one as a silver assay and the other as a gold assay, to find the absolute quantity of each metal, after which the report is made on gold singly, to which is added the report of the silver separately. Thus, if he finds 4 oz. of gold, and 3 oz. of silver, he reports *worse* 14 carats (2 carats being equivalent to an assay ounce, and consequently the 4 oz. of gold equal to 8 carats, which subtracted from 22 carats, the gold standard, leaves 14), to which report he adds, *fine silver* 3 oz. But when the mixed metal contains more than half alloy, it is called *metal for gold and silver*, and the absolute quantity of each is reported separately.

Having made the reader acquainted with these details, we shall now proceed to explain the process of assaying silver, commonly known by the name of *cupellation*.

When we have an assay of silver to make, we flatten the Assay portion of metal upon a polished anvil; the face of the of silver. flattening hammer is also highly polished, that the metal may receive no extraneous matter whatever. The piece of metal is flattened to about the thinness of a sixpence, and an assay pound is cut from it, and most accurately weighed in such scales as we have already noticed. This assay pound is then enveloped in a sheet of lead, which is flattened from a lead bullet, and circular, but made into a funnel shape, in order to contain the silver; and the more nicely to prevent any portion of the silver from being lost, the corners of this leaden funnel are closely and firmly folded down. If the assay master has 45, or, indeed, any number short of 45, they are ranged according to their number upon the table, fig. 13. When the furnace and cupels have been prepared according to the number of assays to be made, and when the proper degree of heat has been attained, the assays are charged into the cupels; and the following method is followed in this part of the process:—In the first instance, a ball of lead is charged into each cupel, with the charging tongs (fig. 12), and its weight is according to the quality of the silver to be assayed, the assayer keeping a stock of leaden bullets of different weights for the purpose. As soon as this lead is melted, which is instantaneous, the assays of silver enveloped in lead are also charged into the cupels. The mass is very soon in complete fusion. The mouth of the muffle, which had before been partially closed with cylinders of charcoal about six or seven inches long, and of different diameters suitable to the convenience of the assayers, as represented in fig. 8, is now nearly closed by smaller cylinders of charcoal. The object of this precaution is, that the stream of air admitted to pass over the surface of the cupels, and which is indispensably necessary for the oxidation of the lead in the process of cupellation, may not chill the muffle and retard the progress of the assay. The oxidation of the metal will proceed with more or less rapidity, according as the stream of air admitted is great or small, and which the assayer has it always in his power to regulate at pleasure. The work already referred to in this article has so beautifully and accurately described

Assaying. the progressive appearance of the assay process of silver, that we cannot do better than quote the description:—
 “The melted metal begins to send off dense fumes, and a minute stream of red fused matter is seen perpetually flowing from the top of the globule down its sides to the surface of the cupel, through which it sinks and is lost to view. This fume and the stream of melted matter consists of the lead oxidated by the heat and air, in one case volatilized, in the other vitrified; and in sinking through the cupel it carries down with it the copper or other alloy of the silver. In proportion to the violence of the heat is the density of the fume, the violence with which it is given off, the convexity of the surface of the globule of melted matter, and the rapidity with which the vitrified oxide *circulates* (as it is termed) or falls down the sides of the metal. As the cupellation advances, the melted button becomes rounder, its surface becomes streaky with large bright points of the fused oxide, which moves with increased rapidity, till at last the globule, being now freed from all the lead and other alloy, suddenly *lightens*; the last portions of litharge on the surface disappear with great rapidity, showing the melted metal bright with iridescent colours, which directly after becomes opaque, and suddenly appears brilliant, clean, and white, as if a curtain had been withdrawn from it. The operation being now finished, and the silver left pure, the cupel is allowed to cool gradually, till the globule of silver is fixed, after which it is taken out of the cupel while still hot, and when cold weighed with as much accuracy as at first. The difference between the globule and the silver at first put in shows the quantity of alloy, the globule being now perfectly pure silver if the operation has been well performed. The reason of cooling the globule or button gradually is, that pure silver, when congealing, assumes a crystalline texture; and if the outer surface is too suddenly fixed, it forcibly contracts on the still fluid part in the centre, causing it to spurt out in aborescent shoots, by which some minute portions are often thrown out of the cupel, and the assay spoiled.” (Aikin's *Dictionary*.)

Assay of gold.

The assaying of gold, preparatory to the parting process, which we are about to describe, is exactly the same as in the case of silver; the object in the process of cupellation being to destroy the base metal or alloy contained in the gold. If gold contained only copper as alloy, the assaying of gold would be as simple and expeditious as that of silver; but all gold contains a portion of silver, which, though reckoned as alloy, cannot, as we have already seen, be destroyed by cupellation. Recourse is had to the process commonly called the parting process, to get rid of the silver contained in the gold. This is done by means of nitric acid, which entirely dissolves the silver, and leaves the gold perfectly pure. The quantity of silver which gold generally contains is too small to allow the nitric acid to act upon it without addition; and the general allowance by assayers is two or three parts of silver to one of gold. If the quantity of silver greatly exceeded these proportions, the operation would not succeed so well; the fine gold would be obtained in the state of brown powder, the particles having been too minutely divided by the excess of silver.

When assays of gold have passed the test, by which all the alloy, excepting silver, has been destroyed, it is in this process that the additional quantity of silver is added. Suppose, for example, that a gold assay is made from the integer, or pound, weighing 12 grains Troy, an addition of from 24 to 36 grains of pure silver is made in addition to the small portion already supposed to exist in the mass. This becomes thoroughly incorporated with the gold in the process of cupellation. The globule or button, as soon as it is taken from the furnace, is passed

between a pair of polished steel rollers, and drawn out into a thin lamina or plate of the thickness of a sixpence, and returned into the furnace to be annealed. After being kept in a red heat for some time, it is taken out and suffered to cool. It is then wound up into a cornet. This is put into a glass matrass, of the shape of an inverted cone, and with about twice or thrice its weight of very pure nitric acid. M. Vauquelin recommends it to be 1.25 specific gravity. But the true test of its strength is in the working of the process. The assayer's attention being directed to the point of strength that will maintain the gold when the silver is extracted in the spiral form, if the acid were too strong, or the silver in too great excess, the gold, as we have already mentioned, would be reduced to powder; and considerable danger exists that it would not be accurately collected, by which an imperfect result would be obtained. The glass matrass is placed upon a sand heat or bath, which is generally a square or oblong pan of copper, with from one to two inches of dry sand in the bottom. The pan is placed over a small square furnace, in which is burning charcoal or coke. As soon as the acid is warm it begins to act upon the silver, and a dense stream of nitrous gas is disengaged. As long as the acid continues to act, the metal appears everywhere to be studded with very minute bubbles, which issue in jets. The disappearance of these, or their uniting into a few large ones, is a sign or mark that the acid has ceased to act. The disappearance also of the nitrous fumes is an indication that the acid has no silver to act upon. In the course of fifteen or twenty minutes the process is finished. But, in order to extend the last portions of silver which the mixture may contain, a small quantity of highly concentrated acid is poured upon the cornet, and boiled, by which the last portions of the silver are extracted. The cornets of gold are thoroughly corroded, but retain the same form, having lost all the silver to two thirds or three fourths of their weight; they are slender and brittle, as we observed before. It is an object of considerable importance to prevent the cornets from being broken, the result being more likely to be accurate than having the gold in fragments; and to prevent this, the quantity of silver used is no more than is absolutely necessary, it being obvious that the less the quantity of gold compared to the silver used in the assay, the more likely is the gold to be broken into pieces.

The hot acid is poured very carefully from the matrass, and warm water is added to wash any remain of silver from the gold, and the addition repeated until the water comes off perfectly clear. The cornets of gold, which are of a dull brown colour and unmetallic appearance, are then put according to their numbers into small clay crucibles, into which they are allowed gently to fall by inverting the matrass, with a portion of water in it, which breaks their fall, and also collects any grains of gold that may be in the matrass. The water is then poured off, and they are put into the furnace, and annealed under a bright cherry heat. When cooled, the pieces of gold have regained their beautiful metallic lustre, and possess all the softness and flexibility of this truly noble metal.

The pieces of gold, thus thoroughly purified, are carefully and accurately weighed, the absolute loss in weight indicating the purity of the metal assayed.

It is a matter of the greatest importance that the silver used in this process should contain no gold, otherwise a source of very material error would arise in the delicate operations of the assayer. Silver generally contains a small portion of gold. Spanish dollars, for example, are found to contain about 4 troy grains in the pound, and are generally preferred in the parting process upon the large scale; but assayers in general use silver revived from a

precipitation of the nitrate of silver, which they are sure contains no gold.

The nitrate of silver is precipitated by immersing in it plates of copper, which throw down the silver in the metallic state. It may also be recovered by a solution of common salt, which converts the silver into luna cornea, of which, when washed and well dried, 100 parts contain 75 of silver. The accuracy of the assay may also be proved by this process. The luna cornea, however, is more difficult to reduce to the metallic state, and the mode of recovery by plates of copper is always preferred.

So that each assay, on an average, was performed in $11\frac{1}{2}$ minutes, and the charcoal used did not much exceed $\frac{1}{4}$ th of a pound weight. The standard of the silver used in these experiments was proved by an assay in the ordinary furnace to be 949 millièmes, and the average result by the new furnace was 948.75 millièmes, a difference not more than occurs in the use of the large furnace, and an object of no importance in point of accuracy.

Experiments were also tried with this small furnace, to prove the highest degree of heat that could be produced; and two balls of Wedgwood's pyrometer were put into the

It remains for us now briefly to mention the process of assaying by the *Petit Fourneau à Coupelle* of Messrs Anfrye and d'Arcet. This process is the same in principle, in all respects, as that which we have been detailing. The only difference consists in the greater facility of the process, and the comparative diminution in the fuel used. The furnace first used by these gentlemen had a small pair of bellows attached to it (see fig. 16); and after the furnace was brought to a proper degree of heat, which required two hours and a half, the following was the result of the experiments made.

furnace, which, when cold, indicated, the one 35, the other 30 degrees, and is fully equal to the heat of the ordinary assay furnace.

When Messrs Anfrye and d'Arcet had improved their furnace by adopting a tube of iron in place of the bellows, they could raise the proper degree of heat in the furnace in half an hour, which required by the original construction two hours and a half.

The following experiments were made upon some five-franc pieces, the standard of which, according to law, should have been from 897 to 903 milimètres :

Termes Moyens.	1 Gram.	7 Gram.	14.33 Min.	901 Mill.	139.33 qrs.

These experiments differ very little from those we have already stated, a trifling increase in the duration of the assay, and in the charcoal consumed, being the only difference; and the greater facility which this furnace has of being raised to the necessary degree of heat, before the assays are charged into the cupels, more than compensates for the increased duration of the assay and charcoal consumed.

This small furnace is particularly recommended for the service of the *Bureaux de Garantie de Province*, where a limited number of assays are from time to time made; and, in point of economy, presents many advantages to recommend it to a place in the chemical laboratory.

This furnace may also be used for a melting furnace; and to convert it to this purpose, the muffle is taken out, and the various apertures, which are open when the assays are making, closed by their respective stoppers: a stand may then be put upon the grate, and a crucible of such size as the furnace will admit, placed upon it, and which can very readily and conveniently be done from the opening *h*, fig. 15. In this use of the furnace coke may be employed instead of the charcoal, the heat being greater and more steady with the former than the latter. (E. E.)

ASSELYN, JOHN, a famous painter, was born in Holland, and became the disciple of Isaiah Vandervelde, the battle-painter. He distinguished himself in history-painting, battles, landscapes, animals, and particularly horses.

He travelled into France and Italy, and was so pleased with the manner of Bambochio that he always followed it. He painted many pictures at Lyons, where he married the daughter of a merchant of Antwerp, and returned with her to Holland. Here he first discovered to his countrymen a fresh and clear manner of painting landscapes like Claude Lorraine; upon which all the painters imitated his style, and reformed the dark brown they had hitherto followed. Asselyn's pictures were so much admired at Amsterdam that they sold there at a high price. He died in that city in 1660. Twenty-four pieces of landscapes and ruins, which he painted in Italy, have been engraved by Perelle.

ASSEMBLY, the meeting of several persons in the same place, upon the same design. Assemblies of the clergy are called *convocations*, *synods*, *councils*. The annual meeting of the church of Scotland is called a *General Assembly*.

ASSEN, a town of the Netherlands, capital of the province of Drenthe, containing 1173 inhabitants. It is a lively and pleasant place, being on the road between Groningen and Zwolle.

ASSENDE, a market-town, with 3314 inhabitants, in the circle of Ceclo and province of East Flanders. It is in long. 3. 59. 22. E. and lat. 51. 13. 49. N.

ASSENHEIM, a jurisdiction belonging to the mediatized Count of Solme Rodelheim, now in the dominions of

Assaying
Assenheim.

process of
assaying.

Assens
||
Assideans.

the prince of Hesse Cassel, in Germany, containing one city, ten villages, 654 houses, and 3957 inhabitants. The chief place of the bailiwick is of the same name, and contains 615 inhabitants.

ASSENS, a sea-port town of Denmark, situated upon the Little Belt, a strait of the Baltic which separates the isle of Funen from the continent. It is the common passage from the duchy of Sleswick to Copenhagen. Long. 10. 30. E. Lat. 55. 15. N.

ASSER, JOHN, or ASSERTUS MENEVENSI, that is, *Asser of St David's*, bishop of Sherburn in the reign of Alfred the Great. He was born in Pembrokeshire in South Wales, and educated in the monastery of St David's by the archbishop Asserius, who, according to Leland, was his kinsman. In this monastery he became a monk, and by his assiduous application soon acquired universal fame as a person of profound learning and great abilities. Alfred, the munificent patron of genius, about the year 880 sent for him to court. The king was then at Dean in Wiltshire. He was so charmed with Asser that he made him his preceptor and companion. As a reward for his services, he appointed him abbot of two or three different monasteries; and at last promoted him to the episcopal see of Sherburn, where he died and was buried in the year 910. He was, says Pitts, a man of happy genius, wonderful modesty, extensive learning, and great integrity of life. He is said to have been principally instrumental in persuading the king to restore the university of Oxford to its pristine dignity and lustre. He wrote *De Vita et Rebus Gestis Alfredi*, first published by Archbishop Parker in the old Saxon character, at the end of *Walsinghami Hist.* Lond. 1574. It was reprinted at Frankfort in 1603, in folio, and in 8vo at Oxford in 1722. Various other works have been ascribed to this author by Pitts and by Leland.

ASSESSOR, an inferior officer of justice, appointed chiefly to assist the ordinary judge with his opinion and advice.

ASSETS, in *English Law*, are real or personal. Where a man hath lands in fee-simple, and dies seised thereof, the lands which come to his heirs are assets real; and where he dies possessed of any personal estate, the goods which come to the executors are assets personal.

ASSHETON, WILLIAM, doctor of divinity, and rector of Beckenham in Kent, was born in the year 1641, and was educated at Brazen-nose College, Oxford. After entering into orders he became chaplain to the duke of Ormond, and was admitted doctor of divinity in 1673. Soon after he was nominated to a prebend in the church of York, presented to the living of St Antholin, London, and to the rectory of Beckenham in Kent. He was the first projector of the scheme for providing for clergymen's widows and others, by a jointure payable out of the mercers' company. He wrote several pieces against the papists and dissenters, and some devotional tracts. He died at Beckenham in September 1711, in the 70th year of his age.

ASSIDEANS, or CHASIDÆANS (from the Hebrew *chasidim*, merciful, pious), those Jews who resorted to Mattathias to fight for the law of God and the liberties of their country. They were men of great valour and zeal, having voluntarily devoted themselves to a more strict observance of the law than other men; for after the return of the Jews from the Babylonish captivity there were two sorts of men in their church,—those who contented themselves with that obedience only which was prescribed by the law of Moses, and who were called *Zadikim*, i. e. the *righteous*,—and those who, over and above the law, superadded the constitutions and traditions of the elders, and other rigorous observances: these latter were called *Chasidim*, i. e. the *pious*. From the former sprung the

Samaritans, Sadducees, and Caraites; from the latter the Pharisees and the Essenes.

ASSIENTO, a Spanish word signifying a *farm*, in commerce, is used to denote a treaty between the king of Spain and other powers, for importing negroes into the Spanish dominions in America.

ASSIGNATION, in the law of Scotland, is the term applied to the transference of a right by deed of conveyance.

ASSIMILATION, in *Physics*, is that motion by which bodies convert other bodies into their own substance and nature.

ASSIN, an African country of considerable extent, situated in the interior, now comprehended under the dominion of Ashantee.

ASSISSI, a city in the delegation of Perugia, in the papal territory of Italy. It contains 20 churches, 12 monasteries for begging friars, and about 4000 inhabitants, mostly poor, and depending for subsistence on the saintly devotees, who, to the number of many thousands, make annual pilgrimages to the cathedral, which contains the tomb of St Francis, the founder of the Franciscan order. Long. 12. 29. 23. E. Lat. 43. 4. 22. N.

ASSITHMENT, a wiregeld, or composition, by a pecuniary mulct; from the preposition *ad*, and the Sax. *siþe*, *vice*; *quod vice supplicii ad expiandum delictum solvitur*.

ASSIZE, in old English law-books, is defined to be an assembly of knights and other substantial men, together with a justice, in a certain place and at a certain time; but the word, in its present acceptation, implies a court, place, or time, when and where processes, whether civil or criminal, are decided by judge and jury.

ASSOCIATION, the act of associating or constituting a society or partnership, in order to carry on some scheme, affair, or business, with more advantage. The word is Latin, *associatio*; and compounded of *ad*, to, and *socio*, to join.

ASSOCIATION OF IDEAS. See METAPHYSICS.

ASSODNAGUR, a town of Hindostan, in the province of Bejapoor, the capital of a Mahratta district of the same name, 68 miles S.E. from Poonah. Long. 74. 55. E. Lat. 18. 6. N.

ASSOILZIE, in *Law*, to absolve or free by sentence of court.

ASSONANCE, in *Rhetoric* and *Poetry*, a term used where the words of a phrase or a verse have the same sound or termination, and yet make no proper rhyme. These are usually accounted vicious in English, though the Romans sometimes used them with elegance, as *Militem comparavit, exercitum ordinavit, aciem lustravit*.

ASSONANT RHYMES is a term particularly applied to a kind of verses common among the Spaniards, where a resemblance of sound serves instead of a natural rhyme. Thus *ligera, cubierta, tierra, mesa*, may answer each other in a kind of *assonant* rhyme, having each an *e* in the penult syllable, and an *a* in the last.

ASSUMPSIT, in the *Law of England*, a voluntary promise, whereby a person assumes or takes upon him to perform or pay any thing to another.

ASSUMPTION, a festival in the Romish church, in honour of the miraculous ascent of the Virgin Mary into heaven. The Greek church also observes this festival, and celebrates it on the 15th of August with great ceremony.

ASSUMPTION, in *Logic*, is the minor or second proposition in a categorical syllogism.

ASSUMPTION, or ASSONGONG, one of the Marianne or Ladrone Islands, in the Pacific Ocean, of a conical figure, and 600 feet in height. It is of a dreary aspect, and almost totally covered with lava from the eruptions of a volcano in the centre. It has no anchorage near the shore. Long. 140. 55. E. Lat. 19. 45. N.

Assiento
||
Assump-
tion.

ASSUMPTION, an island in North America, in the Gulf of St Lawrence, at the mouth of the great river of the same name. Long. 60. 40. W. Lat. 49. 30. N.

ASSUMPTION, the capital city of the province of Paraguay in South America. It is situated on an obtuse angle formed by the eastern bank of the river Paraguay, 18 miles above the junction of the first mouth of the Pilcomayo, and 48 above that of the second. It was originally a small fort, but, from the convenience of its situation, in a few years it became a city, and in 1547 was erected into a bishopric. The adjacent territory is rich and fertile in a high degree, and abounds in a great variety of fruits. The air is temperate and the climate salubrious; the trees are perpetually green, and the rich pastures in the neighbourhood feed numerous flocks of cattle. The city is inhabited by Spaniards, Indians, and Mestizoes, who trade in hides, tobacco, and sugar. The Paraguay affords a channel of communication between Buenos Ayres and this place; but the passage is long, owing to the rapid flow of the waters of that river: this, however, is considerably obviated by the favourable winds which blow from the south for a great part of the year. Long. 59. 35. W. Lat. 24. 47. S.

ASSUMPTIVE ARMS, in *Heraldry*, are such as a person has a right to assume with the approbation of his sovereign and of the heralds.

ASSURANCE, or **INSURANCE**. See **INSURANCE**.

ASSYE, a small town of Hindostan, in the province of Berar, 24 miles N.N.E. from Jalnapoor, noted for a battle fought near it in September 1803, between a force of 4500 men under General Wellesley, afterwards the Duke of Wellington, and the combined armies of Sindia and the rajah of Nagpoor, amounting to 30,000 men, in which the British were victorious, though with severe loss. Long. 76. 40. E. Lat. 20. 14. N.

ASSYN-KALESI, a village of Asia Minor, in Caria, occupying a peninsula among the branches of Mount Grius, with a mean but extensive fortress on the summit of the rock. This village stands on the site of the ancient Jasus, a considerable city, and many antiquities are still to be seen in it. Some of the most spacious sepulchres are at present inhabited by Greek families as their ordinary dwellings. Long. 27. 32. E. Lat. 37. 18. N.

ASSYRIA, an ancient kingdom of Asia, concerning the commencement, duration, and extent of which historians are not agreed. Ctesias and Diodorus Siculus describe the Assyrian monarchy, under Ninus and Semiramis, as of very great extent; but the silence of Homer, and the brief statements of Herodotus, are not easily reconciled with this opinion; and there is no mention of the greatness of Assyria in the history of the judges and succeeding kings of Israel, though during that period the latter kingdom was oppressed and enslaved by different powers. According to Ptolemy, Assyria was bounded on the north by Armenia Major, on the west by the Tigris, on the south by Susiana, and on the east by Media; but the name is generally used in a more comprehensive sense, so as to include Mesopotamia, and sometimes even Babylonia and Chaldea. The most common account of the origin and revolutions of the Assyrian monarchy is the following:—The founder of it was Ashur, the second son of Shem, who, removing out of Shinar, either by the appointment of Nimrod or to elude the fury of a tyrant, conducted a large body of adventurers into Assyria, and laid the foundation of Nineveh (Gen. x. 11). These events happened not long after Nimrod had established the Chaldean monarchy, and fixed his residence at Babylon. The Persian historians suppose that the kings of Persia of the first dynasty were the same with the kings of Assyria, of whom Zohah or Nimrod was the founder of Babel. It does not, however, ap-

pear that Nimrod reigned in Assyria. The kingdoms of Babylon and Assyria were originally distinct and separate (Micah v. 6); and in this state they remained until Ninus conquered Babylon and made it tributary to the Assyrian empire. Ninus, the successor of Ashur (Gen. x. 11. Diod. Sic. lib. 1), seized on Chaldea after the death of Nimrod, and united the kingdoms of Assyria and Babylon. This great prince is said to have subdued Asia, Persia, Media, Egypt, and other countries. If he did so, the effects of his conquests were of no duration; for in the days of Abraham we do not find that any of the neighbouring kingdoms were subject to Assyria. He was succeeded by Semiramis, a princess of a heroic mind; bold, enterprising, fortunate; but of whom many fabulous things have been recorded. It appears, however, that there were two princesses of the same name, who flourished at very different periods. Whether there was an uninterrupted series of kings from Ninus to Sardanapalus or not, is still a question. Some suspicion has arisen that the list which Ctesias has given of the Assyrian kings is not genuine; for many names in it are of Persian, Egyptian, and Grecian extraction. Nothing memorable has been recorded concerning the successors of Ninus and Semiramis. Of that effeminate race of princes it is barely said that they ascended the throne, lived in indolence, and died in their palace at Nineveh. Diodorus (lib. ii.) relates, that, in the reign of Teutames, the Assyrians, solicited by Priam their vassal, sent to the Trojans a supply of 20,000 foot and 200 chariots, under the command of Memnon, son of Tithonus president of Persia. But the truth of his relation is rendered more than doubtful by the accounts of other writers. Sardanapalus was the last of the ancient Assyrian kings. Contemning his indolent and voluptuous course of life, Arbaces, governor of Media, withdrew his allegiance, and rose up in rebellion against him. He was encouraged in this revolt by the advice and assistance of Belesis, a Chaldean priest, who engaged the Babylonians to follow the example of the Medes. These powerful provinces, aided by the Persians and other allies, who despised the effeminacy or dreaded the tyranny of their Assyrian lords, attacked the empire on all sides. Their most vigorous efforts were in the beginning unsuccessful. Firm and determined, however, in their opposition, they at length prevailed, defeated the Assyrian army, besieged Sardanapalus in his capital, which they demolished, and became masters of the empire, B. C. 821.

After the death of Sardanapalus the Assyrian empire was divided into three kingdoms, viz. the Median, Assyrian, and Babylonian. Arbaces retained the supreme power and authority, and fixed his residence at Ecbatana, in Media. He nominated governors in Assyria and Babylon, who were honoured with the title of *kings*, while they remained subject and tributary to the Median monarchs. Belesis received the government of Babylon as the reward of his services, and Pul was intrusted with that of Assyria. The Assyrian governor gradually enlarged the boundaries of his kingdom. He invaded Israel, and compelled the usurper Menahem to relinquish the independency of his kingdom, and pay 1000 talents of silver. It is probable that other nations submitted to the power of his arms. The Syrians were either propitiated by an alliance, or reduced by compulsion, to allow his army to cross their country on his invasion of Israel, for through it he must have marched. On Nabonasser he bestowed the sovereignty of Babylon, and left his elder son Tiglath-pileser heir of his Assyrian dominions. This prince also invaded Israel, and carried more than one of the ten tribes captive to Assyria. The dominions of Ahaz king of Judah being invaded by the confederate hosts of the kings of Israel and Syria, that prince despoiled the temple of

Astabat
||
Astara.

its gold and silver, and, along with the treasure of his palace, purchased the support of Tiglath-pileser, who, entering the Syrian dominions, vanquished and slew their monarch, and fulfilled the predictions of the prophets Isaiah and Amos, by bringing that ancient kingdom to an end. Tiglath-pileser died in the midst of his career of victory, and was succeeded by Shalmaneser, who carried the war into the dominions of Hoshea king of Israel, whom he reduced to submission, imposing an annual tribute upon the kingdom. Hoshea, in attempting to shake off this yoke, again brought upon himself the vengeance of Shalmaneser, who once more subjected the country, and laid siege to Samaria, which capitulated after a defence of three years. Hoshea was put in chains and thrown into prison, and the inhabitants were led into captivity. Hezekiah, king of Judah, also set at defiance the power of Assyria by refusing tribute; but he chose the time for this revolt with greater judgment than Hoshea. The Assyrians were at that period engaged in an unsuccessful war with the Tyrians, during the prosecution of which Shalmaneser died, and was succeeded by Sennacherib, who invaded Judah; upon which Hezekiah, to purchase peace, sent him all the gold and silver with which the temple, as well as his own house, was decorated. The treaty, however, was no sooner concluded than it was trampled upon by Sennacherib, who sent an army to besiege Jerusalem. But the leaders, while haranguing the people who were upon the walls, blasphemed against God, for which, as the sacred historian informs us, they were signally punished, 185,000 of the Assyrians being cut off in one night by the angel of the Lord. This terrible destruction forced him back to his own dominions, where he exercised such tyranny over his subjects that he was assassinated by two of his own sons. Esarhaddon, his third son, ascended the throne, and extended the Assyrian dominions by the conquest of Babylon, Israel, and Syria, and the subjugation of Judah, Egypt and Ethiopia. After the death of Esarhaddon only a few princes appear to have ascended the throne of Assyria, and the kingdom at last was split, and annexed to those of Media and Babylon. Several tributary princes afterwards reigned in Nineveh; but no particular account of them is found in the annals of ancient nations. We hear no more of the kings of Assyria, but of those of Babylon. Cyaxares king of Media assisted Nebuchadnezzar king of Babylon in the siege of Nineveh, which they took and destroyed B. C. 606. The Chaldean or Babylonish kingdom was transferred to the Medes after the reign of Nabonadius, son of Evilmerodach, and grandson of Nebuchadnezzar. He is styled Belshazzar in the sacred records, and was conquered by Cyrus B. C. 538.

ASTABAT, a town of Persian Armenia, situated near the river Aras, the ancient Araxes, 20 miles south-east of Nacsvan. It is a small but neat place, and each house is supplied with a well of water. The neighbouring country is fertile, and produces good wine. There is a root peculiar to this country, called *ronas*, used for dyeing red, great quantities of which are cultivated by the inhabitants and exported to India. Long. 46. 30. E. Lat. 39. N.

ASTAFORT, a town of France, in Gascony. It is the head of a canton in the department of the Lot and Garonne, arrondissement of Agen, and contains 4140 inhabitants.

ASTANDA, in *Antiquity*, a royal courier or messenger, the same with ANGARUS. King Darius of Persia is said by Plutarch, in his book on the fortune of Alexander, to have formerly been an *astanda*.

ASTARA, a town of Persia, and capital of a district, the governor of which is independent of Ghilan and Schirvan. It is situated on the river Astara. 70 miles N. of Reshd, and 100 E. of Tabriz. Long. 49. E. Lat. 38. 20. N.

ASTARAKAT, a town of Persia; in the province of Segistan or Seistan. 100 miles N. of Zareng; 220 W.N.W. of Candahar.

ASTAROTH, or ASHTAROTH, in *Antiquity*, a goddess of the Sidonians. The word is Syriac, and signifies *sheep*, especially when their udders are turgid with milk. From the fecundity of these animals, which in Syria continue to breed a long time, they formed the notion of a deity, whom they called *Astaroth* or *Astarte*. Solomon, in compliment to one of his queens, erected an altar to her. In the reign of Ahab, Jezebel caused her worship to be performed with much pomp and ceremony; she had 400 priests; the women were employed in weaving hangings or tabernacles for her; and Jeremiah observes, that "the children gathered the wood, the fathers kindled the fire, and the women kneaded the dough, to make cakes for the queen of heaven."

ASTELL, MARY, an English authoress of some name, was born at Newcastle-upon-Tyne in the year 1668. Her father, who was a merchant, committed the education of his daughter to her uncle, who was a clergyman. Convinced of the general injury done to young ladies at that period by the deficiency of their education, he taught her the Latin and French languages, and instructed her in the principles of logic, mathematics, and natural philosophy. Having spent 20 years of her life in Newcastle, she went to London, where she continued the pursuit of her studies; and, deeply affected with the general ignorance of her sex, she employed the first fruits of her pen to rouse them to a proper emulation, in a work entitled *A Serious Proposal to the Ladies, wherein a Method is offered for the Improvement of their Minds*, printed in 12mo, at London, 1697. The chief object of this work was to recommend the erection of a seminary for female education. She next wrote a book entitled *Reflections on Marriage*, which was published in 1700. This lady was a zealous advocate for the religious system commonly called *orthodox*, and in politics defended the doctrine of non-resistance. About this time she published some controversial pieces, among which are the following:—*Moderation Truly Stated*; *A Fair Way with the Dissenters*; *An Impartial Enquiry into the Causes of the Rebellion*; and *A Vindication of the Royal Martyrs*; all printed in 4to, in 1704. Her most finished performance was, *The Christian Religion*, as professed by a Daughter of the Church of England; published in 1705, in a large octavo volume. She died in the year 1731.

ASTELL'S ISLAND, one of the English Company's islands, at the north-west part of the Gulf of Carpentaria, of moderate height, and wooded. Iron ore is found here. Lat. 11. 55. S.

ASTERIA or STAR-STONE. This name is given to certain varieties of the perfect corundum, when cut in a peculiar manner. The structure of this gem is that of a hexagonal prism, surmounted by a double hexagonal pyramid, which, when cut perpendicular to the axis, and rounded off in the form of a ring-stone, very often presents, when held up to a strong light, a distinct star of six rays. This phenomenon frequently occurs in sapphires and rubies, and, when perfect, the gem is highly prized.

The same name has been given to the joints of an extraneous fossil, merely from the form they present.

ASTERISK, a mark in form of a star (*), placed over a word or sentence, to refer the reader to the margin, or elsewhere, for a quotation, explanation, or the like.

ASTERN, a sea phrase, used to signify any thing at some distance behind the ship; being the opposite of AHEAD, which signifies the space before her.

ASTI, a province of the duchy of Piedmont, in the

Astarakat
||
Asti.

continental dominions of the king of Sardinia. It is bounded on the north-east and east by Alessandria, on the south-east by Aquis, on the south-west by Alba, and on the west and north-west by Turin. It extends over 400 square miles, or 256,000 acres. It is a plain, with gentle undulations, watered by the Tanaro and the Po; fruitful in all the productions of Italy, but more especially in corn, wine, and silk. It contains one city and 109 towns and villages, inhabited by 110,623 persons.

ASTI, the capital of the above province, is a large and well-built town, standing on the left bank of the Tanaro, in Upper Italy. It is the see of a bishop, who is a suffragan of the archbishop of Turin. It contains many churches and monastical institutions, with 22,000 inhabitants, who carry on a considerable trade in corn, wine, and silk, which is not a little promoted by the situation of the town on the high road from Alessandria to Turin and Coni. 20 miles W. of Alessandria, and 24 E. of Turin.

ASTOMI, in anthropology, a people feigned without mouths. Pliny speaks of a nation of Astomi in India, who lived only by the smell or effluvia of bodies taken in by the nose.

ASTORGA, a city of Spain, in the province of Leon, situated on a plain near the river Tuerto, and having the appellation of a marquissate, which title it confers on a noble family. It is surrounded with ancient fortifications, and has near it a castle in ruins. It has a cathedral, being the see of a bishop under the church of Compostella. It was called "the city of priests," from the great numbers of that profession that were formerly resident within its walls. It contains 2000 inhabitants. Long. 5. 38. 53. W. Lat. 42. 27. 9. N.

ASTRABAD, or ASTERABAD, a small province of Persia, sometimes included in that of Mazanderan. It is bounded on the west by the Caspian Sea; to the south it is separated by a lofty ridge of mountains from the districts of Damgan and Bistan; it extends to 58° of east longitude, where it is divided from Dahistan by the river Ashor. The country, although mountainous, and interspersed with deep forests, in which it is scarcely possible to travel, possesses beautiful and fertile valleys, producing rice, wheat, and other grains in abundance, or spread out in a boundless expanse of verdure, the pasturage of numerous flocks and herds. Fraser, who travelled through Persia in 1822, extols in the most lavish terms the appearance of the country. "There is no describing," he observes, "the beauty and richness of these pastures; all is like velvet, smooth and soft, varying only in the height, not in the thickness, of the sward." The soil, with little culture, is exceedingly productive, owing to the abundance of water which irrigates and fertilizes it. But while the province in many parts presents a landscape of luxuriant beauty, it is a prey to the ravages of disease, and the frequent incursions of the surrounding tribes. The heavy torrents which fall in the rainy season stagnate in the forests, forming morasses which, in the heats of summer and autumn, exhale a pestilential vapour, from the decomposition of the vegetable matter they contain. From these seats of noxious effluvia the wandering tribes of shepherds fly beyond the Goorgaun or the Attruck, and live on the verge of the burning sand, although they have to carry water for each day's consumption from the distant river. The better classes retire from the intense heats of summer into the mountains; but the settled inhabitants of the villages, who cannot so easily remove, and who generally remain, suffer severely from sickness. Intermittent and putrid fevers, droupies, and all those ailments which proceed from cold or from unwholesome air, prevail. The inhabitants, notwithstanding the unhealthiness of their climate, are a stout and athletic race. The revenue derived from this pro-

vince by the king of Persia does not exceed the value of L.7000 sterling. It is famous, however, for furnishing a supply of matchlocks, or toffunchees as they are called, from toffuny, a gun or matchlock, with which the troops who generally attend upon the king's person are armed. This is the ancient Hyrcania, and is the native country of the Kadgers, a Turkish tribe, of whom the king is the head, and on whom he considers he can rely in times of danger.

ASTRABAD or ASTERABAD, a town of Persia, the capital of the above province, is situated on the south-east shore of the Caspian Sea, at the mouth of the river Aster or Ester, and at the head of an admirably sheltered bay, extremely convenient for shipping. This bay is formed by a neck of land, varying in breadth from 4 to 12 miles, which runs from a point near Astrabad for about 70 miles eastward, dividing a strip of water from 8 to 40 miles broad from the main body of the Caspian Sea. Astrabad is an ancient city, and owes its origin to Yezzen-ibn-Mess-lub, an Arab chief of great celebrity, who commanded the armies of Soliman, the seventh caliph of the Omniades, about the beginning of the seventh century. It was destroyed by Tamerlane. In 1744 Hanway visited this place, and attempted to open a direct trade with it from Europe. It is a pleasant, well-built town, about 3½ miles in circuit, and highly picturesque in appearance, from the buildings being intermingled with trees and extensive gardens. It was formerly larger, but Nadir Shah contracted it within its present limits. A mound of earth surrounds it, the remains of a mud wall once lofty and formidable, and defended by numerous towers, and also by a wide and deep ditch, now almost filled with rubbish. The only fortification it possesses is a small parapet, supplied with loop-holes for musketry, raised upon the mouldered wall. The streets and lanes are paved with stone, always kept in good repair; and a drain runs down their centre, a provision of infinite importance in this rainy climate, where the torrents which fall and are thus carried off would otherwise plough up and destroy the streets, or be allowed to stagnate in pools. The houses are constructed chiefly of wood, and are frequently furnished with verandas; their style of architecture is light and open, the roofs covered with red tiles, and sometimes with thatch. Many houses are provided with square towers, having openings, such as are used in other eastern towns, for ventilating the rooms. They have a good effect when seen from a distance, presenting the appearance of spires. Astrabad has but little trade; and the bazaars or public markets, though extensive, are but poorly filled, containing little more than the necessary supplies for the consumption of the place. There are no public buildings deserving of notice. The number of houses within the walls is estimated at from 2000 to 3000. The town is extremely unhealthy during the hot weather, owing to the damp and noxious exhalations of the surrounding forests. Astrabad is 400 miles north-east of Ispahan. Long. 54. 25. E. Lat. 36. 50. N.

ASTRACAN, a large city of Asiatic Russia, the seat of an archbishop, built on eminences surrounded by the marshes of the Volga, between 50 and 60 miles from its influx into the Caspian Sea. It is about three miles in circumference, or nearly five miles if we include the suburbs, and is surrounded by a wall mostly in a ruinous condition. This city was anciently the capital of a kingdom belonging to the Tartars, who were expelled in 1554 by the Russian prince Iwan Basilowitz. In 1569 it was besieged by the Turks, who were defeated with great slaughter by the Russians. In 1672 it was seized by the rebel Slenkorazin. Since that period it has suffered from conflagrations, being formerly composed of mean and inconvenient buildings of wood. But in the modern city attention has been paid both to its safety and embellishment, by the

Astrabad
||
Astracan.

Astracan. erection of more spacious and elegant houses and public edifices of stone. The high price of timber has contributed to bring about this improvement, the inhabitants finding it cheaper to use in their modern erections either brick or a species of freestone found in a quarry near the banks of the Volga. Of the public buildings, the most conspicuous are the two commercial halls for the reception and sale of merchandise, both finished in an elegant style of architecture, one of which is appropriated to the Armenians and the other to the Persians. The kremlin, which is uninhabited, stands on a hill, and contains the cathedral, a spacious brick edifice. There are, besides, in this city two convents, twenty-five Russian and one Roman Catholic church. Some votaries of Brahma, natives of Moultan, also reside at Astracan; and the Armenians have a metropolitan church, which is surmounted by a cupola, where, in the course of the worship, Pallas saw exhibited by the suffragan or archimandrite the holy oil prepared in Mount Ararat, and which is held sacred by the inhabitants. In the vicinity of this city are numerous vineyards, which being irrigated by the waters of the Volga, produce abundantly; and a considerable quantity of wine is manufactured, and exported to Petersburg, Moscow, and other places. The situation of Astracan is favourable for trade; and it is accordingly a great commercial mart between Asia and Europe. By means of the river Volga, the commodities of Eastern Asia are carried into the heart of Russia, while the produce of Russia, or European goods imported, are brought down to the Caspian Sea, and transported across to Resht, Lahajan, Balfroosh, and Astrabad, whence they find their way into Persia and the East. Goods are also sent by sea to Mangushluck, on the eastern shore of the Caspian Sea, and thence eastward to Khyvah, a distance of 250 miles, and afterwards to Buckharia, a distance of 250 more. The shipping employed in this trade does not exceed, according to the estimate made by Fraser in his account of the commerce of Persia, 12 vessels of from 50 to 100 tons. These vessels belong to Russian or Mahometan merchants settled at Astracan. Two caravans besides, each of 500 camels, set out from Astracan eastward for Khyvah and Buckharia. The exports from Astracan eastward are iron, steel, copper, quicksilver, leather, furs, cotton, woollen, silk, and other manufactured goods of Europe; and the imports consist of fruits, grain, rice, timber, tobacco, raw hides, lambskins, drugs, turquoises, from Buckharia; silk goods, gold and silver brocades, from Persia; and shawls from Thibet and Cashmere. The fisheries on the Volga, in which are caught the sturgeon and the beluga or great sturgeon, are of great extent and importance. From the sounds of these fish are made isinglass and caviare, the demand for which has been increasing for many years. There is not, except on the banks of Newfoundland, a more productive fishery. During the fasts of the Greek church, which continue for about one third of the year, the sturgeon affords the chief food to European Russia and its populous cities. Many thousands acquire wealth either by fishing or by conveying and retailing the fish in the markets. The population of Astracan is 70,000, composed of Russians, Armenians, Greeks, Tartars, Persians, Jews, Indians, English, and

French; but the most numerous are the Tartars and Armenians. In 1830 the inhabitants suffered severely from the cholera morbus. 330 miles S.S.E. Saratov, 1040 S.S.E. Petersburg. Long. 47. 44. E. Lat. 46. 21. N.

ASTRACAN was formerly the name of an independent government of Asiatic Russia, but in 1785 was incorporated with that of Caucasus. It was of considerable extent, but thinly peopled on account of the barrenness of the soil, except on the banks of the Volga, the Ural, and their tributary streams. (Pallas's *Travels*; Tooke's *Russia*.)

ASTRÆA, in *Astronomy*, a name which some give to the sign Virgo, by others called *Erigone*, and sometimes *Isis*. The poets feign that Justice quitted heaven to reside on earth in the golden age; but growing weary of the iniquities of mankind, she left the earth and returned to heaven, where she commenced a constellation of stars, and from her orb still looks down on the ways of men.

ASTRAGALOMANCY, a species of divination performed by throwing small pieces, with marks corresponding to the letters of the alphabet, the accidental disposition of which formed the answer required. This kind of divination was practised in a temple of Hercules in Achaia. The word is derived from *αστραγαλος*, and *μαντεια*, *divination*.

ASTROGNOSIA, the science of the fixed stars, or the knowledge of their names, constellations, magnitudes, &c.

ASTROLABE, the name for a stereographic projection of the sphere, either upon the plane of the equator, the eye being supposed to be in the pole of the world, or upon the plane of the meridian, when the eye is supposed in the point of the intersection of the equinoctial and horizon.

ASTROLADE is also the name of an instrument formerly used for taking the altitude of the sun or stars at sea.

ASTROLADE, among the ancients, was the same as our armillary sphere.

ASTROLOGY, a pretended science, teaching to judge of the effects and influences of the stars, and to foretel future events by the situation and different aspects of the heavenly bodies.

This science was divided into two branches, *natural* and *judiciary*. To the former belonged the predicting of natural effects; as the changes of weather, winds, storms, hurricanes, thunder, floods, earthquakes, &c. Judiciary or judicial astrology is that which pretended to foretel moral events, as if they were directed by the stars. It is commonly said to have been invented in Chaldea, and thence transmitted to the Egyptians, Greeks, and Romans; though some will have it of Egyptian origin. At Rome the people were so infatuated with it, that the astrologers, or, as they were then called, the *mathematicians*, maintained their ground in spite of all the edicts of the emperors expelling them from the city. The same superstition has prevailed in modern nations. The French historians tell us, that in the time of Queen Catherine d' Medici, astrology was so much in vogue that the most inconsiderable thing was not to be done without consulting the stars. And in the reigns of king Henry III. and IV. of France, the predictions of astrologers were the common theme of the court conversation.

ASTRONOMY.

History. **A**STRONOMY, from *αστρον* or *αστρον*, a star, and *νομος*, a law, is the science which treats of the laws observed by the stars in their motions. By an extension of signification, it embraces every thing that is known relating to the nature and constitution, as well as to the motions, of the celestial bodies.

The present treatise is divided into Four Parts. In the *First*, which contains the HISTORY OF ASTRONOMY, the progressive advancement of the science from the times of the Chaldeans and Egyptians to the present day is briefly sketched, and the labours of those illustrious indi-

viduals commemorated, who have either theoretically or practically contributed most to its progress. The *Second Part*, which we have denominated THEORETICAL ASTRONOMY, is devoted to a general view of the science,—to the explanation of the different theories and methods by which the motions of the celestial bodies are represented, and their places computed; and the description of such facts as observation has made known respecting their nature and constitution. *Part Third* treats of PHYSICAL ASTRONOMY; and *Part Fourth* of PRACTICAL ASTRONOMY. *History.*

PART I.

HISTORY OF ASTRONOMY.

Astronomy, if we dignify by that name the first rude attempts that were made to discover the order and connection of the celestial motions, may probably be regarded as the most ancient of all the sciences. In fact, a certain degree of attention to the heavenly bodies is forced even on the savage who inhabits the forest, and derives his subsistence from the spontaneous productions of the earth. The regular vicissitude of day and night inevitably compels him to observe the diurnal course of the sun; and he cannot fail soon to perceive, that the variety and succession of the seasons is equally dependent on the oblique annual course of the same great luminary. The moon, too, in the absence of the sun, is an object so conspicuous, so consoling, and so useful, that her motions must at all times have been watched with attention and interest; while her various phases, her alternate waxings and wanings, her regular disappearance and return after equal intervals of time, would be contemplated with admiration and delight. Nor are the wonders of the starry firmament less calculated to strike even the most heedless observer of the heavens. The magnificent spectacle of the sky bespangled with brilliant points, and revolving in obedience to eternal and unalterable laws, affords a constant succession of new objects of sublime and exalted contemplation. The occasional recurrence, also, of eclipses and other unusual phenomena, which seem to interrupt the general order and uniformity of the celestial motions, would stimulate to attentive observation; for the vanity of man has in all ages rendered him eager to connect his own destiny with the heavens, while his timidity has prompted him to regard every apparent deviation from the ordinary course of events as an emblem of the wrath, and a precursor of the vengeance, of superior beings.

But though mankind were probably first impelled by motives of mere curiosity to observe the courses of the stars, no great length of time could elapse ere they perceived that the regular and uniform revolutions of the heavens might be rendered subservient to their own wants and conveniences. By the help of the stars the shepherd, during the night, could count the hours, the traveller track his course through the uniform wastes of the desert, and the mariner guide his bark over the ocean: the husbandman, also, learned to regulate his labours by the appearance of certain constellations, which gave him warning of the approaching seasons. The indications de-

rived from the simple observation of such phenomena were doubtless extremely vague; but as civilisation advanced, the necessity of determining accurately the length of the solar year and of the lunar month, in order to regulate the calendar and the religious festivals, led to the accumulation and comparison of different observations, whereby errors were gradually diminished, and the foundations laid of a more perfect acquaintance with the heavenly motions.

Astronomy, presenting so many objects of interesting curiosity, and having so many practical uses, could not fail to be one of the sciences first cultivated by mankind. Its origin is consequently hid amidst the obscurity and traditions of the remotest ages, and is in fact coeval with the origin of society, and the earliest development of the human intellect. The records or traditions of almost every ancient nation furnish some traces of attention to the state of the heavens, and of some rude attempts to discover the laws, the order, and the period of the most remarkable phenomena,—such as eclipses of the sun and moon, the motions of the planets, and the heliacal risings of the principal stars and constellations. The Chaldeans and Egyptians, Chinese and Indians, Gauls and Peruvians, equally regard themselves as the inventors of astronomy; an honour, however, of which Josephus deprives them all, in order to ascribe it to the antediluvian patriarchs. The fables relating to the two columns of brick and marble which these sages are said to have erected, and on which they engraved the elements of their astronomy, to preserve them from the universal destruction by fire and water to which, they are said to have learned from Adam, the earth was doomed, are not worth the trouble of repetition; nor is there any better proof than the assertion of that credulous historian, of their acquaintance with the *annus magnus*, or, as is most probably supposed, the astronomical cycle of 600 years, which brings back the sun and moon to the same points of the heavens so nearly, that its discovery implies a pretty correct knowledge of the solar and lunar motions. Passing over, therefore, those periods that present us only with a scanty detail of traditional observations or unimportant facts, we will proceed to give a brief account of the state of astronomy among some early nations who have undoubtedly contributed to the improvement of the science, or who, at least, have transmitted to future ages some monuments of their

History. astronomical labours, and of their attention to celestial observations.

Astronomy of the Chaldeans, Egyptians, Phœnicians, Chinese, and Indians.

Chaldeans. According to the unanimous testimony of the Greek historians, the earliest traces of astronomical science are to be met with among the Chaldeans and Egyptians. The spacious level and unclouded horizon of Chaldea afforded the utmost facilities for observing the celestial phenomena; and its inhabitants, enjoying the leisure afforded by a pastoral life, and stimulated by the vain desire of obtaining a knowledge of the future from the aspects of the stars, assiduously cultivated astronomy and astrology. By a long series of observations of eclipses, extending, according to the testimony of some authors, over nineteen centuries, or even a longer period, they had discovered the cycle of 223 lunations, or eighteen solar years, which, by bringing back the moon to nearly the same position with respect to her nodes, her perigee, and the sun, brings back the eclipses in the same order. This is supposed to be the period which they distinguished by the name of *Saros*. They had others, to which they gave the names of *Sossos* and *Neros*; but nothing positive is known with regard to their nature or extent. One thing only is certain, which is, that these Chaldaic periods, whatever they were, were founded on no theoretical knowledge of the celestial motions. They were purely empirical, detected by the comparison of recorded observations, and suppose neither theory nor science, unless, indeed, a simple arithmetical operation is to be considered as such; nor is there any reason to suppose that the Chaldeans employed any process of computation whatever in their predictions of eclipses. Having once established their cycle, they were in possession of a simple means of predicting all those which occurred in the course of it, with as great a degree of accuracy as they considered requisite.

The knowledge of these lunisolar periods among the Chaldeans is doubtless of great antiquity. Simplicius, the commentator of Aristotle, asserts that Callisthenes transmitted to Aristotle from Babylon a collection of observations of all the eclipses which had happened during the nineteen centuries that preceded the conquest of Alexander. This relation, however, is at variance with the accounts given by other historians. Epigenes, cited by Seneca and Pliny, who is supposed to have lived shortly before the time of Alexander, mentions observations of 730 years that had been found preserved on columns of brick. Ptolemy also makes mention of certain observations of eclipses that had been brought from Babylon, several of which he had calculated and verified; but the earliest of these ascends only to the year 720 before our era, or to the 26th of Nabonassar; and if either Hipparchus or himself had been acquainted with others of a more ancient date, they would doubtless have employed them in the determination of the mean motion of the moon. From this circumstance it appears probable that the Chaldeans had no observation sufficiently exact to be of any use to astronomy prior to the time of Nabonassar.

According to Apollonius of Myndus, the Chaldeans supposed the comets to be substances of the same nature as the planets; that they are visible only during a portion of their revolutions, and that they re-appear after certain intervals. But this statement, which argues some just notions respecting the celestial bodies, is contradicted by Epigenes, who himself studied among the Chaldeans, and who affirms, that instead of regarding the comets as sub-

jected like the planets to the operation of eternal laws, they attributed their formation to vortices of inflamed matter, supposing them to have only a temporary existence, and to move in random directions through the fields of space. Diodorus says, that they regarded the world as eternal and imperishable, and held that its order is due, not to chance, but to a divine providence; that the planets, which have peculiar motions, announce future events by their various aspects and colours; that they portend rains, tempests, excessive heats; sometimes also the appearance of comets, eclipses, earthquakes, and, in short, whatever has a beneficial or hurtful influence on the fortunes of nations or individuals.

From the few facts that can be gleaned from the vague accounts given by ancient authors of the astronomy of the ancient Chaldeans, it may be inferred that their boasted science was confined to observations of the simplest and rudest kind, neither guided by theory, nor assisted by instruments; for, notwithstanding the assertion of Herodotus, it is doubtful if they were acquainted even with the gnomon, the simplest of all instruments for determining the obliquity of the ecliptic, the altitude of the pole, and the length of the tropical year. If to the knowledge of their lunisolar periods, the result of ages of observation, we add the notion of a spherical revolution about an inclined axis, and an idea of the principal circles of the sphere and the position of the poles, the sum will comprehend all that constituted the science of a people regarded by antiquity as having made the greatest progress in the science of the stars. Astronomy, however, owes some obligations to their humble labours. The observations which they recorded served to correct the theories that were afterwards imagined by the more brilliant genius of the Greeks, and thereby furnished some materials for the edifice of the world.

The Egyptians were in ancient times the rivals of the Chaldeans in the cultivation of astronomy; and although they have left behind them still fewer monuments of their labours, they have obtained, through the exaggerated statements of the Greeks, even a greater reputation. The Greeks acknowledge themselves indebted to the Egyptians for their science and civilisation; but regarding themselves likewise as descendants of that ancient people, they indulged their vain-glory in magnifying the accounts of the antiquity and knowledge of their supposed ancestors. It is not improbable that some traditional observations of the heavens, along with some arts indispensable to society even in its earliest stages, were carried into Europe by tribes migrating from the banks of the Nile; and it is certain that the early philosophers of Greece travelled into Egypt for the purpose of acquiring a more perfect knowledge of astronomy than could be obtained in their own country. But the facts from which it can be inferred that the Egyptians had much to communicate, are few and ill attested. They are also blended with so much absurdity and fable, that no accurate notions can be formed, from the accounts that have been transmitted to us, of the real advances which that people had made in astronomical science. The priests were the depositaries of the national knowledge; and they carefully concealed it from the vulgar by shrouding it in allegories, traces of which, it has been remarked, may be detected in the institutions even of the present day.

According to Diogenes Laertius, the Egyptians reckoned 48,853 years from Vulcan to Alexander, during which they had observed 373 eclipses of the sun, and 832 of the moon. These numbers in fact nearly express the relative proportion of the eclipses of the two luminaries; but the enormous length of the period altogether exceeds

the bounds of credibility; and it has been remarked that the same number of eclipses might have been observed within the more probable period of twelve or thirteen centuries. Supposing the numbers to be accurately stated, it will follow that, as the observations terminated with the conquest of Alexander, the Egyptians must have been in the habit of observing eclipses at least 1600 years before the commencement of our era. By attentively observing the heliacal rising of the star Sirius, to which they gave the name of Thaat, or Thoth (the Watch-Dog), because its appearance shortly preceded the overflow of the waters of the Nile, the Egyptians had discovered that the year consists of $365\frac{1}{4}$ days. This was their religious or sacred year. Their civil year consisted of only 365 days; consequently the sacrifices and feasts, which were regulated by it, successively corresponded to the different seasons. Instead of attempting to obviate this inconvenience by intercalation, they imposed an oath on their kings to maintain the use of the civil year, superstitiously imagining that each of the seasons would be blessed and rendered prosperous by enjoying in its turn the celebration of the feast of Isis. The difference between the lengths of the sacred and civil year suggested to them their famous sothic or canicular period of 1460 solar years, corresponding to 1461 civil years of 365 days, and which consequently brings back the months and festivals to the same seasons. Dion Cassius ascribes the week to the Egyptians, and says that they first dedicated a day to each of the planets; but it is sufficiently proved that this short cycle was in use among the Chinese and Indians from the remotest times, and was even known to the Druids of Gaul and Britain. It was more probably suggested to different nations by the phases of the moon. The Egyptians had likewise been attentive to the courses of the planets. Diodorus Siculus affirms that they could explain the phenomena of the stations and retrogradations; and Macrobius ascribes to them the knowledge of the real motions of Mercury and Venus, and says that they regarded these planets as satellites of the sun. This notion would do credit to their philosophy; but it is unfortunately not mentioned by any other author, and for this reason the testimony of Macrobius is suspected. The state of their practical astronomy may in some measure be inferred from the means they employed to determine the magnitude of the sun's apparent diameter. By comparing the time, observed by means of a clepsydra, which the sun takes to mount above the horizon at the equinox, with that in which he makes a complete revolution of the sky, they estimated his diameter at $28' 48''$. An observation of this kind is liable to great uncertainty; and as there is no evidence that the Egyptians possessed the slightest knowledge of spherical trigonometry, they would probably make no allowance for the obliquity of the equator to their horizon; and if this correction was left out of the calculation, as it probably was, their diameter, already too small, ought to have been still farther reduced, and to have amounted only to $24' 42''$. It has been conjectured by Goguet, that the obelisks of Egypt were intended to serve the purpose of gnomons; and this conjecture acquires some probability from their needle-shaped form, and the narrowness of their bases relatively to their heights. It has however been proved by MM. Jollois and Devilliers, in their description of Thebes, that the obelisks were connected with the walls of temples and palaces; a disposition which rendered them entirely unfit for the purposes of astronomical observation. Their summits were also of so unfavourable a form, that the Romans were obliged to surmount them with a ball in order to obtain a distinct and well-defined shadow. The pyramids have also been adduced as evidences of the

early progress of astronomy among the Egyptians; for the faces of these stupendous masses are turned directly towards the four cardinal points, from which it is evident that the people by whom they were constructed were at least acquainted with the method of tracing a meridional line.

From this brief account it appears, that the only circumstances with which we are acquainted that imply the knowledge of astronomical methods among the Egyptians, are the length of the year, the doubtful discovery of the true motions of Mercury and Venus, and the position of the pyramids. The Chaldean observations were of use to Hipparchus and Ptolemy in the determination of some important elements; but those of the Egyptians exercised no influence whatever on the future progress of the science.

The Phœnicians are also generally enumerated among the nations who cultivated astronomy at a very early period, though it does not appear, from any facts mentioned by ancient authors, that they addicted themselves to the observation of the heavens, or made any discoveries relative to the motions of the planets. That they excelled in the art of navigation is certain, from the commercial intercourse which they carried on with many places on the coasts of Africa and Spain, and in the principal islands of the Mediterranean; and it may readily be allowed that in their long voyages they would direct their course during the night by the circumpolar stars. If they had any speculative notions of astronomy, these were probably derived from the Chaldeans or Egyptians.

In China, astronomy has been cultivated from the remotest ages, and always been considered as a science indispensably necessary to the civil government of the state. The Chinese boast of a series of eclipses, recorded in the annals of the nation, extending over a period of 3858 years, all of which, they pretend, were not only carefully observed, but calculated and figured previous to their occurrence. The same motives which led the Chaldeans and Egyptians to attend to the celestial phenomena, namely, the regulation and division of time, had equal influence among the Chinese; and we accordingly find the care of the calendar occupying the attention of their earliest princes. The emperor Fou-Hi, whose reign commenced about 2857 years before our era, is said to have assiduously studied the motions of the celestial bodies, and laboured to instruct his ignorant subjects in the mysteries of astronomy. But as they were yet in too rude a condition to be able to comprehend his theories, he was obliged to content himself with giving them a rule for the computation of time by means of the numbers 10 and 12, the combination of which produces the cycle of 60 years, which is the standard or unit from which they deduce their hours, days, and months. Tradition is silent with respect to the sources from which Fou-Hi derived his own knowledge. The Chinese attribute to him also the invention of arithmetic and music. In the year 2608 B. C., Hoang-Ti caused an observatory to be built, for the purpose of correcting the calendar, which had already fallen into great confusion, and appointed one set of astronomers to observe the course of the sun, another that of the moon, and a third that of the stars. It was then discovered that the twelve lunar months do not exactly correspond with a solar year; and that, in order to restore the coincidence, it was necessary to intercalate seven lunations in the space of nineteen years. If this fact rested on undoubted evidence, it would follow that the Chinese had anticipated the Greeks by 2000 years in the discovery of the Metonic cycle. The reign of Hoang-Ti is also rendered memorable by the institution of the *Mathematical Tribunal*, for promoting the science of

History. astronomy, and regularly predicting eclipses, to which an extraordinary importance has always been attached in China. The members of this celebrated tribunal were made responsible with their lives for the accuracy of their predictions, by a law of the empire, which ordained that, "whether the instant of the occurrence of any celestial phenomenon was erroneously assigned, or the phenomenon itself not foreseen and predicted, either negligence should be punished with death." In the reign of Tchong-Kang, the two mathematicians of the empire, Ho and Hi, were the victims of this absurd and sanguinary law; an eclipse having taken place which their skill had not enabled them to foresee.

The emperor Yao, who mounted the throne, according to the Chinese annals, about the year 2317 B. C., gave a new impulse to the study of astronomy, which had begun already to decline. He ordered his astronomers to observe with the utmost care the motions of the sun and moon, of the planets and the stars, and to determine the exact length of each of the four seasons. He sent Hi-Tchong to the east to observe the star situated at the point of the vernal equinox, Hi-Tchou to the south to examine that at the summer solstice, Ho-Tchong to the west, and Ho-Tchou to the north, to observe those situated respectively at the autumnal equinox and winter solstice. These docile observers found stars in the positions assigned by the emperor; but the extraordinary resemblance of their names imparts a fabulous air to the whole relation, and excites a very excusable incredulity even with regard to those statements which involve no improbability. To this emperor are attributed the Chinese division of the zodiac into 28 constellations, called the houses of the moon, and the severe laws already noticed in regard to the erroneous prediction of the celestial phenomena.

From the time of Yao the Chinese year consisted of $365\frac{1}{4}$ days. They also divided the circle into $365\frac{1}{4}$ degrees, so that the sun daily described in his orbit an arc of one Chinese degree. Their common lunar year consisted of $364\frac{543}{940}$ days; and by combining this number with $365\frac{1}{4}$, they formed the period of 4617 years, after which the sun and moon again occupy the same relative positions.

The earliest Chinese observations we are acquainted with, sufficiently precise to afford any result useful to astronomy, were made by Tcheou-Kong, whose reign commenced about the year 1100 before our era. Two of these observations are meridional altitudes of the sun, observed with great care at the village of Loyang, at the time of the summer and winter solstices. The obliquity of the ecliptic thus determined at that remote epoch is $23^{\circ} 54' 3.15''$; a result which perfectly agrees with the theory of universal gravitation. Another observation, made about the same time, relates to the position of the winter solstice in the heavens; and it also corresponds to within a minute of a degree with the calculations of Laplace. Laplace considers this extraordinary conformity as an indubitable proof of the authenticity of those ancient observations.

The golden age of Chinese astronomy extended from the reign of Fou-Hi to the year 480 B. C.; that is, over a space of 2500 years. It is only, however, towards the latter part of this long period that the history of China becomes in any degree authentic; and the true date which must be assigned for the commencement of observations on which any reliance can be placed, is the year 722 B. C.; that is, 25 years posterior to the era of Nabonassar. From that period to the year 400 B. C. Confucius reckons a series of 36 eclipses, and of these 31 have been verified by modern astronomers. After this the science

History. fell into great neglect, notwithstanding the inveterate tenacity with which the Chinese in general adhere to their ancient customs. The decline of their astronomy is ascribed, whether justly or not, to the barbarous policy of the emperor Tsin-Chi-Hong-Ti, who, in the year 221 B. C., ordered all the books to be destroyed, excepting those only which related to agriculture, medicine, and astrology, the only sciences which he considered as being of any use to mankind. His fury, it is true, was principally directed against those of Confucius, the stern morality of which he felt to be a censure on his own profligacy; but those of science and astronomy were included in the general destruction. In this manner, it is said, the precious mass of astronomical observations and precepts which had been accumulating for ages was irretrievably lost.

Lieou-Pang, the successor of Tsin-Chi-Hong, endeavoured to repair the disaster, by re-establishing the tribunal of the mathematics, and ordering a new series of observations to be undertaken. About the year 104 B. C. the astronomer Sse-Ma-Tsien gave some precepts for the calculation of eclipses, the motions of the planets, and the syzygies. He employed instruments of copper, the nature and construction of which are however not very well understood, for measuring the extent of the 28 zodiacal constellations; and he observed the meridional altitudes of the sun, by means of a gnomon 8 feet high. The differences of right ascensions, and the intervals between the risings, settings, and culminations of the stars, were measured by clepsydræ. It would appear that after this period astronomical observations continued for some time to be made in China with considerable regularity. In the 164th year of our era the astronomer Tchong-Heng constructed armillary spheres and a celestial globe. He also formed a catalogue of stars, which is said to have contained 2500, but without either latitudes or longitudes; a circumstance which gives us a very unfavourable idea of the state of practical astronomy at that time. About the eighth century of our era, all knowledge of the science seems to have been again lost. The predictions were erroneous; and the Chinese witnessed, with superstitious terror, eclipses of which their astronomers had given them no intimation. This induced the emperor Hieng-Tsong to call to his court the astronomer Y-Hang, by whose indefatigable activity a reform was speedily effected. With a view to determine the situations of the principal places of the empire, this astronomer constructed gnomons, spheres, astrolabes, quadrants, and other instruments; and sent one company of mathematicians to the south, and another to the north, with directions to observe daily the altitudes of the sun and the polar star. The latitudes of the cities were determined by observing the shadow of the gnomon, and the longitudes by eclipses of the moon. Y-Hang had the mortification of announcing two eclipses which did not take place. On these occasions he alleged the usual excuse, namely, that his calculus was not in error, but that the celestial bodies had deviated from their ordinary courses out of respect to the virtues of the emperor. The fate of Ho and Hi had probably suggested to the Chinese astronomers this ingenious mode of disarming the emperor's resentment by flattering his vanity.

On considering attentively the accounts which have been given of the Chinese astronomy, we find that it consisted only in the practice of observations which led to nothing more than the knowledge of a few isolated facts. The missionaries who were sent out by the Jesuits about the end of the seventeenth century, to whom we are indebted for what is known of the early history

History. of China, either seduced by some appearances of truth, or thinking it prudent to conciliate the people whom they were attempting to convert, adopted their marvellous relations regarding the antiquity of their science, and spread them over Europe. As the history of the nation begins to become more authentic, their astronomy shrinks into its real but insignificant dimensions. Superstitiously attached to their ancient usages, and blindly adopting the habits of their ancestors, the Chinese continued to observe the heavens from century to century without making the slightest advances in theoretical knowledge. In later times they have adopted many improvements, for which they are entirely indebted to foreigners. During the time of the caliphs many Mahometans passed into China, carrying with them the astronomical methods and knowledge of the Arabians. The missionaries introduced the science of Europe; and the most that can be said in praise of the Chinese is, that their government sometimes relaxed so far its spirit of jealousy and exclusion, as to afford protection to these strangers, adopt their arts, and place them at the head of the mathematical tribunal.

Indians. The astronomy of the Indians forms one of the most curious problems which the history of science presents to the consideration of the learned, and one which, notwithstanding the numerous dissertations to which it has given rise, still continues involved in great uncertainty. Of the science of the ancient nations, of which we have already spoken, the accounts which have come down to our times are founded on conjecture and tradition; for few monuments remain to confirm or confute the glowing descriptions which authors have given of its high antiquity and great perfection. But the claims of the Indians rest on more solid foundations. We are in possession of the tables from which they compute the eclipses and places of the planets, and of the methods by which they effect the computation: we have, in short, an Indian astronomy committed to writing, which represents the celestial phenomena with considerable exactness, and which, therefore, could only be produced by a people far advanced in science. But the difficulty of the problem consists in determining the sources from which this science originated, and the epoch of its existence; whether it was created by the people who now blindly follow its precepts without understanding its principles, or was communicated to them by another race of a bolder and more original genius, through channels with which we are unacquainted. Some authors regard India as the cradle of all the sciences, particularly of astronomy, which they suppose to have been cultivated there from the remotest ages; others date the origin of the Indian astronomy from the period when Pythagoras travelled into that country, and carried thither the arts and sciences of the Greeks; a third opinion is, that astronomy was conveyed to India by the Arabians in the ninth century of our era, and that the Brahmins are only entitled to the humble merit of adapting the rules and practices of that people to their own peculiar methods of calculation. We shall endeavour to describe very briefly the existing monuments of the Indian astronomy, which furnish the only data from which a rational conjecture can be formed relative to its antiquity and precision.

We possess four different sets of tables of Indian astronomy. The first which were known in Europe were brought from Siam by La Loubère, who had resided in that country as ambassador from Louis XIV. They were communicated by him to the celebrated Cassini, who, notwithstanding the difficulties arising from the complicated and useless operations which they directed, suc-

ceeded in detecting the principles on which they were constructed, and in explaining their use and signification. History. The date of these tables corresponds to the 21st of March in the year 638 of our era. They suppose two species of years, the solar tropical year, which they make to consist of 365 days 5 hours 50 min. and 4 sec., and the solar anomalistic year, that is, the period in which the sun returns to its apogee, which they estimate at 365 days 6 hours 12 min. 36 sec. This determination of the length of the solar year is too great only by 1 min. 15 sec. By means of the same tables the longitudes of the sun and moon are determined with considerable accuracy. They contain a correction for the sun's mean place, which corresponds to the equation of the centre. At 90° from the apogee, where the inequality of the sun's motion is greatest, they estimate the requisite correction at $2^\circ 12'$, which is about $16'$ too great. This determination deserves to be particularly remarked, because, on account of a secular inequality of the eccentricity of the sun's orbit, there was once a time when the greatest value of the equation of the centre was nearly $2^\circ 12'$; and this fact is adduced as a proof of the remote antiquity of the observations from which the tables in question have been constructed. These tables suppose the apogee to retain always the same position relatively to the fixed stars; in reality it advances or gains on the stars about $10''$ annually; but the supposition is still much nearer the truth than in the system of Ptolemy, where the apogee is supposed to be absolutely at rest with regard to the plane of the sun's orbit, and consequently to fall back among the stars by the whole quantity of the precession of the equinoxes, or about $50''$ annually. With regard to the motions of the moon, they are deduced from a period of 19 years, in which are comprehended nearly 235 lunations; so that the cycle of Meton appears to have been known in Siam as well as in China. The moon's apogee is supposed to have been in the beginning of the movable zodiac 621 days after the epoch of the 21st of March 638, and to make an entire revolution in the heavens in the space of 3232 days. The first of these suppositions agrees with Mayer's tables to within a degree, and the second differs from them only by 11 hours 14 min. 31 sec. They contain only one correction for the two principal inequalities of the moon's motion, the equation of the centre and the evection.

A second set of Indian tables was sent from Chrisnabouram, a town in the Carnatic, by Father Du Champ, to De Lisle, about the year 1750. They are fifteen in number. They give the mean motions of the sun, moon, and planets; equations of the centre for the sun and moon; and two corrections for each of the planets, one of which corresponds to the apparent, the other to the real inequality. The epoch of these tables is not so ancient as that of the former. It corresponds to the 10th of March, at sunrise, in the year 1491 of our era, when the sun and moon were in conjunction.

A third set of astronomical tables was sent from India by Father Patonillet, and received by De Lisle about the same time with those of Chrisnabouram. These have not the name of any particular place affixed to them; but being calculated for the latitude of $16^\circ 16'$, Bailly thinks it probable that they came from Narsapour. Their epoch is midnight, between the 17th and 18th of March 1569.

The fourth and last set of Indian tables which we possess have been published in the Memoirs of the Academy of Sciences. They were communicated by a learned Brahmin of Tirvalore, a small town on the Coromandel coast, to the French astronomer Legentil, who had gone to India to observe the transit of Venus in 1769. The tables

History. of Tirvalore, though somewhat different in form, present many points of resemblance with those formerly known in Europe. They suppose the same length of the year, the same inequalities of the sun and moon, and they are adapted nearly to the same meridian. But while they correspond with the other tables in these elements, they differ from them greatly in the antiquity of their epoch, which goes back to the famous era of the Calyougham, that is, the beginning of the year 3102 before Christ.

Now, the only question to be determined with regard to the antiquity of the Indian astronomy is, whether this epoch is real or fictitious; that is, whether the state of the heavens at the commencement of the Calyougham, as assumed in these tables, was actually determined by observation, or computed backwards from observations of more modern date. The solution to this question can only be obtained from the internal evidence afforded by the tables themselves; by examining whether the elements and precepts which they furnish are of sufficient accuracy to enable the places of the sun, moon, and planets to be calculated through a period of 44 centuries, without involving errors which the refined accuracy of the modern tables furnishes the means of detecting. A comparison of the Indian with the modern tables has been made at great length by Bailly, who imagines that he finds ample evidence of the reality of the era in question, and of the existence of an astronomy prior to that period, hardly yielding in accuracy to that which modern science has built on the theory of universal gravitation. The theory of Bailly has been adopted, and put forth with additional clearness and evidence, by the late Professor Playfair. One of the principal arguments which these illustrious authors bring forward in support of it is founded on the longitudes of the sun and moon. The mean place of the moon at the commencement of the Calyougham, that is, at midnight, between the 17th and 18th of February 3102 *b. c.*, is stated by the Indian tables to be 306° . Her mean place, computed from Mayer's tables, without taking into account the acceleration, with which the Indians in the 15th century were of course unacquainted, is $300^{\circ} 51' 16''$. Hence there would be a discrepancy of $5^{\circ} 8' 44''$. But, according to the theory and last tables of Laplace, the moon, in virtue of the acceleration of her mean motion, has passed over an arc of very nearly 6° more than she would have done had her mean motion continued uniform from the period of the Calyougham to the date of Mayer's tables. This added to $300^{\circ} 51' 16''$ gives $306^{\circ} 51' 16''$ for the mean longitude of the moon at the epoch of the Calyougham, differing from the Indian determination by only $51' 16''$. Now, it is argued that this is a degree of accuracy which could have been reached only by actual observation, especially since, if the tables had been computed backwards, the error arising from the acceleration alone would have amounted to more than 5° . Bailly computes the place of the moon at the same epoch, from all the tables, Greek and Arabian, to which the Indians can be supposed to have had access, and the discrepancies are so great as to render his conclusion almost inevitable, that the Indian tables could not possibly have been drawn from such sources. The tables of Ptolemy make the moon's longitude at that time $11^{\circ} 52' 7''$ greater than the Indian tables; and those of Ulugh-Beigh, constructed at Samarcand in 1437, give a difference of 6° also in excess.

Similar results are obtained from the consideration of other elements. According to the tables of Tirvalore, the tropical year consists of 365 days 5 hours 50 min. 35. sec. Lacaille makes it 365 days 5 hours 48 min. 49 sec. The difference is 1 min. 46 sec. Now the tropical

year, being affected by the precession of the equinoxes, *History* is subject to a secular inequality, which, according to the theory of Lagrange, renders it actually shorter by 40.5 sec. at the present time than it was at the commencement of the Calyougham. The error of the Indian tables is thus reduced to 1 min. 5.5 sec. In like manner, the obliquity of the ecliptic, which has been gradually diminishing during a great number of centuries, is supposed in the Indian tables to be greater than it is now found to be by observation. The Brahmins estimate it at 24° . The formula of Lagrange makes the variation, in 4800 years, amount to $22' 32''$. This therefore must be added to its obliquity in 1700, that is, to $23^{\circ} 28' 41''$, in order to have the true obliquity at the commencement of the Calyougham. The sum is $23^{\circ} 51' 13''$, and falls short of the Indian determination by $8' 47''$. We shall mention only another element, the equation of the centre of the sun. Bailly calculates that, according to the theory of Lagrange, the equation of the sun's centre, at the epoch of the tables, was $2^{\circ} 6' 28''$. The Indians make it $2^{\circ} 10' 32''$. The difference is only about $4'$, and incomparably less than could have resulted from calculation by any methods which we can suppose the Indians to have possessed.

These arguments, it must be admitted, are exceedingly specious, but they are not by any means convincing. Even with the best modern tables we could not, as Bailly himself acknowledges, answer for the accuracy of the places of the sun and moon computed for so remote an epoch. The corrections for the secular inequalities amount in that long period to considerable quantities; and these corrections are deduced by theory from elements with respect to which there exists great uncertainty. And if we cannot be sure of the true places by computing backwards from our own tables, with what degree of confidence can we pronounce upon the accuracy of the places assigned in the tables of the Indians? It may be said that comparisons of this kind can never be supposed to give results perfectly alike. Granted: but if the discrepancies are such that the lapse of a thousand years more or less is required to establish a rigorous conformity, what becomes of the famous epoch of the Calyougham? Some of the elements of the Indian tables could not have the values assigned to them but at a long period before that epoch. In order to find their equation of the sun's centre, for example, it is necessary, according to the results of modern theory, to go back to 6000 years before our era. The argument, therefore, proves too much, and is consequently inconclusive. The different sets of tables of which we have spoken are closely allied with each other, and the most probable supposition is, that they are all derived from those of Chrisnabouram, of which the epoch is 1491. At that era the Indians were acquainted with the instruments, the geometry, and the researches of the Arabians and Greeks. Through this channel the tables seem to have come into their possession. The Brahmins adapted them to their own particular methods of computation, and threw back their epoch to the period when, according to these tables, all the planets were in conjunction with the sun. Every circumstance connected with the science of the Indians conspires to give us the humblest ideas of its value. Their methods of computation are encumbered with the unnecessary multiplications and divisions of enormous numbers, endless additions, subtractions, and reductions, for the purpose of obtaining numbers which could be put into technical verses, and even adapted to songs; so that the astronomer might be enabled to effect his calculations from memory alone, without its being necessary to have

History. recourse to fables or books. But simple and rude as these methods are, if they were really invented by the Brahmans, the science of that people must have greatly retrograded; for at present they merely follow a blind routine, utterly ignorant of theory, or the principles on which their processes are founded. Their astronomy, whether of ancient or recent origin, has produced no effect whatever on that of Europe; it has no filiation or connection with the science of the present day, and therefore has no other claim on our attention than such as may result from motives of mere curiosity.¹

Astronomy of the Greeks.

The origin of astronomy in Greece, as in other early nations, ascends beyond the period of authentic history, and is concealed amidst the fables and traditions of the remotest times. During the darkness of the heroic ages some gleams of an acquaintance with the motions of the stars occasionally burst forth; and some traces appear of astronomical observations, probably derived from Egypt, the country which also furnished Greece with its gods and its arts. The Greeks seem to have divided the heavens into constellations about 13 or 14 centuries before the Christian era; for the sphere of Eudoxus, which is probably one of the fruits of the famous voyage of the Argonauts, must be referred to that period. Their early attention to the appearances of the heavens is sufficiently attested by their mythological fables, the greater part of which are only allegories of the celestial motions, and of the operations of nature. The lively fancy and brilliant imagination of this ingenious people strewed flowers in the most rugged paths, and spread agreeable images over the driest and most uninviting subjects: hence the sky was quickly covered with legends of the loves and exploits of gods and heroes. It would be foreign to our present purpose to enter into an enumeration of these fables, or attempt to trace their connection with the first dawnings of astronomy: we shall content ourselves with barely alluding to Uranus, to Atlas and his son Hesperus, who gave his name to the planet Venus; also to his daughters the Atlantides, from whom the Pleiades received their appellation; to Endymion, who, on the summit of Mount Latmos, held nocturnal converse with the chaste Diana; to Hercules; and Chiron the centaur, who taught men the use of the constellations; Musæus, who imagined the figures of men and animals which cover the celestial sphere; Orpheus and Linus, who explained the theogonies; Atreus, from whose banquet the sun fled back with horror; and Tiresias, who was struck blind for having witnessed some secret of the gods.

The true foundations of Grecian science were laid by Thales, who was born at Miletus 640 years before our era. He was descended from an illustrious family, which had formerly reigned in Phœnicia, and inherited an ample fortune, which he expended in collecting the expiring embers of oriental science. Instigated by the love of knowledge, he travelled first into Crete, and afterwards into Egypt, where he was initiated into the mysteries of the priests, to whom, in return, he is said to have taught the method of measuring the height of the pyramids by comparing their shadows with those of known objects. Returned to his own country, he publicly taught the truths he had collected during his travels, and formed a

History. sect which has been distinguished by the title of the *Ionian School*. His doctrines regarding astronomy contain a few truths which do honour to his sagacity and observation, though they are mixed with much error and absurdity. He taught that the stars are formed of fire; that the moon receives her light from the sun, and is invisible at her conjunctions, because she is hid in the sun's rays. He also taught the sphericity of the earth, which he placed at the centre of the world. He divided the sphere into five zones, by the arctic and antarctic circles, and the two tropics; and held that the equator is cut obliquely by the ecliptic, and perpendicularly by the meridian. He is also said to have observed eclipses; and Herodotus relates that he predicted the famous one which put a stop to the war between the Medes and the Lydians. It does not appear, however, that he ventured to assign either the day or the month of the eclipse, so that his prediction must have been confined to the year. According to Callimachus, he determined the positions of the stars which form the Lesser Bear, by which the Phœnicians guided themselves in their voyages. It is difficult, however, to conceive how Thales, unacquainted with instruments, could determine the positions of stars with so much accuracy as to render any essential assistance to the navigator. It is probable that he only pointed out the configuration, and some of the more brilliant stars of that constellation, among which he might remark that which is nearest the pole of the world.

Thales was succeeded by Anaximander, to whom is also attributed the invention of the sphere, and the knowledge of the zodiac. According to Diogenes Laertius, 610 B.C. he supposed, like his master Thales, the earth to be spherical, and placed at the centre of the universe; but Plutarch ascribes to him the less philosophical opinion of its resemblance to a column. He supposed the sun to be of equal magnitude with the earth. He invented the gnomon, and placed one at Lacedæmon to observe the solstices and equinoxes. But the circumstance which does most honour to Anaximander, and which entitles him to the gratitude of posterity, is the invention of geographical charts. He is said also to have believed in the plurality of worlds,—a sublime idea, which was adopted by almost every succeeding philosopher of Greece.

Anaximenes succeeded Anaximander in the Ionian school, and maintained nearly the same doctrines. Pliny says he was the first who taught the art of constructing dials,—an invention which, as we have just seen, has also been ascribed to Anaximander. These two philosophers probably revived the knowledge of an instrument the use of which had been forgotten amidst the general rudeness and ignorance of their countrymen. Before their time the Greeks only marked the divisions of the day by the different lengths of the sun's shadow.

Anaxagoras was the disciple and successor of Anaximenes. If this philosopher really entertained the ridiculous opinions ascribed to him by Plutarch, the Ionian school must rather have retrograded than advanced in sound philosophy from the time of Thales. He is said to have believed that the sun is a mass of red-hot iron, or of heated stone, somewhat bigger than the Peloponnesus,—that the heaven is a vault of stones, which is prevented from tumbling only by the rapidity of its circular motion,—and that the sun is prevented from advancing beyond the tropics by a thick and dense atmosphere, which forces

¹ For an account of the Indian astronomy, see Bailly, *Astronomie Indienne*; also a Memoir by Professor Playfair, in the *Edinburgh Transactions*, vol. ii., or in the 3d volume of his Works; and the Papers of Jones, Bently, and Davis, in the *Calcutta Memoirs*. The theory of Bailly is most satisfactorily refuted by Delambre. See his *Histoire de l'Astronomie Ancienne*, tom. i.

History. him to retrace his course. These absurd notions are probably greatly exaggerated; but it does not appear that Anaxagoras contributed much to extend the knowledge of the heavens. A melancholy interest is, however, excited in his behalf, on account of the persecution which he suffered in consequence of his liberal opinions and his disregard for the superstitious notions of his age. Having shown the reason of the eclipses of the moon, he was accused of ascribing to natural causes the attributes and power of the gods. Having taught the existence of only one God, he was accused of impiety and treason towards his country. Sentence of death was pronounced on the philosopher and all his family; and it required the powerful interest of his friend and disciple Pericles to obtain a commutation of this iniquitous sentence into one of perpetual banishment.

Pythagoras, born 580 B.C.

While the Ionian sect was so successfully employed in cultivating and propagating a knowledge of nature in Greece, another, still more celebrated, was founded in Italy by Pythagoras. This renowned philosopher was in early youth a disciple of Thales. In quest of knowledge, which in those days could only be obtained by visiting the sages of foreign lands, he travelled into Egypt, Phœnicia, Chaldea, and India, where his memory is said still to subsist. Through the favour of Amadis, king of Egypt, to whom he was recommended by Polycrates, the tyrant of Samos, he was admitted into the sacred college at Memphis, though with great reluctance on the part of the priests. The severe ordeal through which these charlatans compelled him to pass, before they would consent to initiate him into their mysteries, was sufficient to have deterred the most courageous votary of knowledge; and Pythagoras was probably the only stranger who ever succeeded in fully exploring their secrets. After an absence of thirty years he returned to Greece, and began to give instructions in his native island of Samos. Soon after, he passed over to the Grecian colony established at Tarentum in Italy, and settled at Crotona, where he speedily acquired a splendid reputation. He was the first who assumed the modest title of *philosopher*, or lover of wisdom: formerly those who devoted themselves to the acquisition of learning were called *sophists* or *sages*.

Pythagoras is said to have acquired in Egypt the knowledge of the obliquity of the ecliptic, and that of the identity of the morning and evening stars. What he chiefly deserves to be commemorated for in the history of astronomy, is his philosophical doctrine regarding the motion of the earth. He taught publicly that the earth is placed at the centre of the universe; but among his chosen disciples he propagated the doctrine that the sun occupies the centre of the planetary world, and that the earth is a planet circulating about the sun. This system, which still retains his name, being called the old or Pythagorean system of the universe, is that which was revived by Copernicus. It is, however, only just to the memory of this last mentioned great man to observe, that there is a vast difference between the bare statement of the possibility of a fact, and the demonstration of its existence by irrefragable arguments. Pythagoras having remarked the relation which subsists between the tone of a musical chord and the rapidity of its vibration, was led by analogy to extend the same relation to the planets, and to suppose that they emit sounds proportional to their respective distances, and form a celestial concert too melo-

dious to affect the gross organs of mankind. Another fancy into which he was led by his passion for analogies, was the application of the five geometrical solids to the elements of the world. The cube symbolically represented the earth; the pyramid, fire; the octaedron, air; the icosaedron, or twenty-sided figure, water; and the dodecaedron, or figure with twelve faces, the exterior sphere of the universe. Pythagoras left no writings; and it is doubtful whether he really entertained many of the opinions and reveries which have usually been ascribed to him.

Philolaus of Crotona, a disciple of Pythagoras, embraced the doctrine of his master with regard to the revolution of the earth about the sun. He supposed the sun to be a disk of glass which reflects the light of the world. He made the lunar month consist of $29\frac{1}{2}$ days, the lunar year of 354 days, and the solar year of $365\frac{1}{4}$ days.

Nicetas of Syracuse seems to have been the first who openly taught the Pythagorean system of the universe. Cicero, on the authority of Theophrastus, the ancient historian of astronomy, gives him the credit of maintaining that the apparent motion of the stars arises from the diurnal motion of the earth about its axis;¹ but this rational doctrine seems to have been first broached by Heraclides of Pontus, and Ecphantus, a disciple of Pythagoras.

The introduction of the Metonic cycle forms an era in the history of the early astronomy of Greece. The Chal-deans, as we have already stated, established several lunar periods; and the difficulty of reconciling the motions of the sun and moon, or of assigning a period at the end of which these two luminaries again occupy the same positions relatively to the stars, had long embarrassed those who had the care of regulating the festivals. Meton and Euctemon had the honour of first obviating this difficulty, at least for a time; for the motions of the sun and moon being incommensurable, no period can be assigned which will bring them back to precisely the same situations. These two astronomers formed a cycle of nineteen lunar years, twelve of which contained each 12 lunations, and the seven others each 13, which they intercalated among the former. It had long been known that the synodic month consisted of $29\frac{1}{2}$ days nearly; and in order to avoid the fraction, it had been usual to make the twelve synodic months, which compose the solar year, to consist of 29 and 30 days alternately; the former being called *deficient* and the latter *full* months. Meton made his period to consist of 125 full and 110 deficient months, which gives 6940 days for the 235 lunations, and is nearly equal to 19 solar years. This cycle commenced on the 16th of July in the year 433 B.C. It was received with acclamation by the people assembled at the Olympic games, and adopted in all the cities and colonies of Greece. It was also engraved in golden letters on tables of brass, whence it received the appellation of the *golden number*, and has been the basis of the calendars of all the nations of modern Europe. It is still in ecclesiastical use, with such modifications as time has rendered necessary.

Eudoxus of Cnidus, about the year 370 B.C., obtained great reputation as an astronomer. According to Pliny, he introduced the year of $365\frac{1}{4}$ days into Greece. Archimedes says that he supposed the diameter of the sun to be nine times greater than that of the moon, which shows that he had in some degree overcome the illusions

¹ "Nicetas Syracusius, ut ait Theophrastus, cœlum, solem, lunam, stellas, supra denique omnia, stare censet; neque, præter terram, rem ullam in mundo moveri; quæ cum circum axem se summa celeritate convertat et torqueat, eadem effici omnia, quasi, stante terra, cœlum moveretur." (Cicero, *Acad. Quæst.*: *Opera*, tom. iv. p. 39, edit. Bipont.) Copernicus himself could not have stated the doctrine with greater precision.

History. of sense. The titles of three of his works have been preserved—the *Period or Circumference of the Earth*, the *Phenomena*, and the *Mirror*. His observatory was still standing at Cnidus in the time of Strabo. His memory deserves to be honoured for the contempt which he evinced for the Chaldean predictions, and for having contributed to separate true astronomy from the reveries of judicial astrology. Eudoxus seems to have been the first who attempted to give a mechanical explanation of the apparent motions of the planets. He supposed each planet to occupy a particular part of the heavens, and that the path which it describes is determined by the combined motion of several spheres performed in different directions. The sun and moon had each three spheres; one revolving round an axis which passes through the poles of the world, and which occasions the diurnal motion; a second revolving round the poles of the ecliptic, in a contrary direction, and causing the annual and monthly revolutions; the third revolving in a direction perpendicular to the first, and causing the changes of declination. Each of the planets had a fourth sphere to explain the stations and retrogradations. As new inequalities and motions were discovered, new spheres were added, till the machinery became so complicated as to be altogether unintelligible.

Plato. Although Plato can hardly be cited as an astronomer, yet the progress of the science was accelerated by means of the lights struck out by his sublime and penetrating genius. He seems to have had just notions of the causes of eclipses; and he imagined that the celestial bodies originally moved in straight lines, but that gravity altered their directions, and compelled them to move in curves. He proposed to astronomers the problem of representing the courses of the stars and planets by circular and regular motions. Geometry was assiduously cultivated in the school of Plato; and on this account he claims a distinguished place among the promoters of true astronomy.

Aristotle, born 384, died 322, B.C. Astronomy is also under some obligations to Aristotle. In a treatise which he composed on this science, he recorded a number of observations which he had made; and, among others, mentions an eclipse of Mars by the moon, and the occultation of a star in the constellation Gemini by the planet Jupiter. As such phenomena are of rare occurrence, their observation proves that he had paid considerable attention to the planetary motions.

Helicon. A great number of astronomers about this time appear on the stage, whose labours and observations prepared the way for the reformation of the science which was shortly after effected by Hipparchus. Helicon of Cizicene is renowned for the prediction of an eclipse, which took place, as Plutarch affirms, at the time announced. History records the names of only three individuals in ancient Greece who predicted eclipses, Thales, Helicon, and Eudemus. Eudemus composed a history of astronomy, a fragment of which, consisting of only a few lines, is preserved by Fabricius in the *Bibliotheca Græca*. In this it is mentioned that the axes of the ecliptic and equator are separated from each other by the side of a pentodecagon, which is equivalent to saying that they contain an angle of 24°. This is the first value which we find assigned by the Greeks to the obliquity of the ecliptic. It is given in round numbers, and may easily be supposed to contain an error of a quarter of a degree.

Calippus. Calippus is celebrated for the period which he formed of four Metonic cycles. Having observed, by means of an eclipse of the moon which took place about six years before the death of Alexander, that the Metonic cycle contained an error of a fourth of a day, he introduced the period of 940 lunations, containing four Metonic cy-

cles, diminished by one day. He likewise formed a collection of observations on the heliacal risings of the planets. Theophrastus wrote a history of astronomy, and Theophrastus supposed the milky way to be produced by the imperfect junction of the two hemispheres, which allowed the light to penetrate from the firmament beyond. Autolycus of Pitaneas wrote two books, one on the movable sphere, the other on the risings and settings of the stars. These are the most ancient of the astronomical works of the Greeks which have come down to our times.

Pytheas. Pytheas of Marseilles, about the time of Alexander the Great, determined the length of the solstitial shadows in various countries by means of the gnomon. He found the shadows equal at Marseilles and Byzantium—a circumstance which does not give a favourable idea of the accuracy of his observations, inasmuch as the difference of the latitudes of the two places amounts to 2½ degrees. The observation is, however, interesting, as it is the most ancient of the kind which has been preserved after that of Tchou-Kong, and as it confirms the successive diminution of the obliquity of the ecliptic. Pytheas undertook several voyages for the purpose of obtaining geographical and astronomical information, and advanced northwards as far as Iceland. His relations have been treated as fabulous by Strabo and Polybius, but the accuracy of the greater number of them has been confirmed by modern observation and experience. He was the first who distinguished the climates by the different lengths of the days and nights.

Astronomy in the School of Alexandria.

In the history of the various sects which have hitherto come under our review, we meet only with some useful remarks, with numerous hypotheses and conjectures, but with scarcely any appearance of regular and connected science. Up to this date the astronomical knowledge of the Greeks was confined to a few facts, the discovery of which implies no theory, and scarcely the aid even of the simplest instruments. The order and arrangement of the planets, the causes of eclipses, the identity of the morning and evening stars, the approximate length of the year, that of the lunar month, the obliquity of the ecliptic, and the cycles of Meton and Calippus, were almost the sole results of their astronomical speculations. In the Alexandrian school we meet for the first time with regular and systematic observations. We there find angular distances measured with appropriate instruments, and calculations made according to the rules of trigonometry.

After the premature death of Alexander, his principal generals shared among themselves his magnificent conquests, and Egypt fell to the lot of Ptolemy Soter. This prince was distinguished by an ardent love of science, and a desire to promote every species of liberal knowledge. He accordingly invited to his court, which he had established at Alexandria, the most eminent philosophers of Greece, and fixed them there by his liberality and munificent protection. His son, Ptolemy Philadelphus, who inherited his throne, also inherited his genius and love of science and learning. A superb edifice, styled the *Museum*, was assigned to the use of the men of science whom he had attracted to his capital, to which he also added an observatory, and the famous library, which had been collected with great care and at a vast expense by Demetrius Phalerius. The prince took great delight in the Museum; he visited it frequently, entered into familiar conversation with its inmates on the subject of their various pursuits, and by his own example stimulated their

History. zeal and encouraged their inquiries. This noble institution, which survived all the vicissitudes of nine centuries, was the means of conferring incalculable benefits on the human race; and the name of its founder, Ptolemy Philadelphus, will be gratefully remembered while science and learning occupy a place in the estimation of mankind.

Aristillus and Timo-
charis, 300
B. C. The first astronomers of the Alexandrian school were Aristillus and Timocharis, who flourished under the first Ptolemy, about 300 years before Christ. The chief object of their labours was the determination of the relative positions of the principal stars of the zodiac, instead of merely announcing their risings and settings, as had been the practice of the orientals and the ancient Greeks. The observations of these two astronomers conducted Hipparchus to the important discovery of the precession of the equinoxes, and served as the basis of the theory which Ptolemy, some centuries afterwards, gave of that phenomenon.

Aristar-
chus, B. C.
281. Aristarchus of Samos, the next in order of the Alexandrian astronomers, composed a treatise on the *Magnitudes* and *Distances* of the sun and moon, which has been preserved to our times. In this treatise he describes an ingenious method which he employed to obtain the relative distances of the two luminaries. At the instant when the moon is dichotomized, that is, when the exact half of her disk appears to a spectator on the earth to be illuminated by the sun's light, the visual ray passing from the centre of the moon to the eye of the observer is perpendicular to the line which joins the centre of the moon and sun. At that instant, therefore, he measured the angular distance of the two bodies, and finding it to be 87 degrees, he concluded, by the resolution of a right-angled triangle, that the distance of the sun is between eighteen and nineteen times greater than that of the moon. This method is perfectly correct in theory, but it is difficult to be assured of the exact instant of the moon's dichotomy, and in an angle of such magnitude a very small error greatly affects the result. The error of Aristarchus is very considerable, the true angle being about 87° 50'. The estimated distance of the sun is by consequence far too small; yet the determination, faulty as it was, contributed to expand greatly the existing notions relative to the boundaries of the universe, for the Pythagoreans had taught that the sun is only three, or at most three and a half times more distant than the moon. Another delicate observation made by Aristarchus was that of the magnitude of the sun's diameter, which, as we learn from Archimedes, he determined to be the 720th part of the circumference of the circle which the sun describes in his diurnal revolution. This estimate is not very far from the truth, and the observation is by no means an easy one. He embraced the doctrine of Pythagoras respecting the earth's motion, and appears to have entertained juster notions than any of the astronomers who preceded him, on the magnitude and extent of the universe. The treatise on the *Magnitudes* and *Distances* is published in the third volume of the works of Dr Wallis, with a Latin translation by Commandine, and some notes.

Erato-
sthenes,
born 276
B. C. Eratosthenes, the successor of Aristarchus, was a native of Cyrene, and invited to Alexandria by Ptolemy Evergetes, who appointed him keeper of the royal library. He is supposed to have been the inventor of armillary spheres, a species of instrument extensively used by the ancient astronomers. By means of an instrument of this kind he observed the distance between the tropics to be to the whole circumference of a great circle as 11 to 83; a ratio equivalent to 47° 42' 39", half of which gives 23°

51' 19.5" for the obliquity of the ecliptic. This is a very important observation, and confirms the gradual diminution of the obliquity as indicated by theory. Eratosthenes is celebrated for being the first who attempted, on correct principles, to determine the magnitude of the earth. Having remarked, by some means with which we are unacquainted, that Syene, the most southern of the cities of ancient Egypt, is situated nearly on the same meridian with Alexandria, he conceived the idea of determining the amplitude of the celestial arch intercepted between the zeniths of the two places, and of measuring at the same time their distance on the ground; operations which would afford data for the determination of the whole length of the terrestrial meridian. Syene was known to be situated exactly under the tropic; for at the summer solstice the gnomon had no shadow, and the sun's rays illumined the bottom of a deep well in that city. On the day of the solstice he found the meridional distance of the sun from the zenith of Alexandria to be 7° 12', or a fiftieth part of the circumference. It had also been ascertained by the *benatists* or surveyors of Alexander and the Ptolemies, that the itinerary distance between Alexandria and Syene was 5000 stadia; therefore $5000 \times 50 = 250,000$ stadia form the circumference of a great circle of the earth, or the length of the terrestrial meridian. Unfortunately, on account of the uncertainty respecting the length of the stadium here employed, we possess no means of estimating the degree of approximation afforded by this rude though ingenious attempt; but the idea does immortal honour to Eratosthenes, and the moderns have added nothing to his method: their better success is owing solely to the progress of the arts and the perfection of astronomical instruments.

About this time the science of astronomy was enriched by the discoveries of some of the distinguished geometricians whose labours have so greatly extended the glory of the Alexandrian school. Euclid, the celebrated author of the *Elements*, lived in the reign of the first Ptolemy. He composed a book on the sphere, which probably served as a model for future works of the same kind, and was the first who treated in a geometrical manner of the phenomena of the different inclinations of the sphere. Conon of Samos, the friend of Archimedes, collected the records of eclipses, which had been observed by the ancient Egyptians; and Callimachus ascribes to him the constellation of Berenice's hair. Archimedes, whose profound genius and deep knowledge of geometry and mechanics entitle him to the appellation of the *Newton* of the ancients, also claims a high rank among the cultivators of astronomy. His celebrated planetarium, which represented the motions of the sun, moon, planets, and starry sphere, has been a frequent theme of the admiration and praises of the poets:

Jura poli, rerumque fidem, legesque deorum,
Ecce Syracusius transtulit arte senex.

Apollonius of Perga solved the important problem of the stations and retrogradations of the planets by means of epicycles and deferents; and he is entitled to the glory of having formed the alliance between the two sciences of geometry and astronomy, which has been productive of the greatest advantages to both.

Astronomy, which had as yet only consisted of a knowledge of isolated facts, acquired a systematic form, and almost a new existence, from the genius and assiduity of Hipparchus, one of the most astonishing men of antiquity, and perhaps the greatest of all in the sciences which are not purely speculative. This illustrious founder of astronomical science was born at Nice in Bythia, and ob-

History. served at Rhodes. Flamsteed and Cassini, probably misled by some ambiguous expressions of Ptolemy, have related that his observations were made at Alexandria; and this opinion seems generally to have been adopted by historians. The question has been examined carefully, and at considerable length, by Delambre (*Astronomie Ancienne*), who comes to the conclusion that there is no reason whatever to infer that Hipparchus ever saw Alexandria. Ptolemy, in reporting the observations of Hipparchus, supposed Rhodes and Alexandria to be situated on the same meridian, and consequently does not find it necessary to mention the place at which the observations were made.

Hipparchus commenced his brilliant career by verifying the determination of the obliquity of the ecliptic made by Eratosthenes. He next directed his attention to the length of the tropical year. By comparing an observation of his own, of the summer solstice, with a similar one made by Aristarchus 140 years before, he found that the anciently received value of $365\frac{1}{4}$ days was too great by seven minutes. This leaves the tropical year a value still too great; but it is probable that the error arose from the inaccuracy of the observation of Aristarchus: for the observations of Hipparchus, compared with those of the moderns, make the length of the tropical year amount to 365 days, 5 hours, and 49 minutes, which is only 12 seconds greater than the truth. By a careful observation of the solstices and equinoxes, he discovered that the year is not divided by these points into four equal parts, the sun occupying $94\frac{1}{2}$ days in passing from the vernal equinox to the summer solstice, and only $92\frac{1}{2}$ from the same solstice to the equinox of autumn. The sun, consequently, remained 187 days in that part of the ecliptic which lies between the equator and the north pole, and therefore only about 178 in the other part. This observation led Hipparchus to the great discovery of the eccentricity of the solar orbit. He accounted for the apparent inequality of the sun's motion, by supposing that the earth is not placed exactly at the centre of the circular orbit of the sun, and that consequently his distance from the earth is subject to variation. When the sun is at his greatest distance, he appears to move more slowly; and when he approaches nearer, his motion becomes more rapid. The distance of the earth from the centre of the orbit is called the *eccentricity*: it produces an equation between the real and apparent motions, which is called the *equation of the centre*. He determined the magnitude of this equation in terms of the radius of the ecliptic, and fixed the position of the line of the apsides, or that which joins the two opposite points of the orbit which are at the greatest and least distance from the earth. With these data he formed the first tables of the sun which are mentioned in the history of astronomy. The discovery of the eccentricity also led Hipparchus to that of the inequality of the lengths of the solar days at different seasons of the year. In the interval which elapses between the sun's passage over the meridian and his return to it the following day, the sun advances by his own proper motion towards the east nearly a degree. But the rate of this motion is unequal, varying between 57 and 61 minutes of a degree; and the accumulation of the inequalities forms what is called the equation of time, that is, the difference between the true time, as shown by the sun, and the mean time, shown by a well-regulated clock, the motions of which are equal and uniform.

The attention of Hipparchus was next directed to the motions of the moon; and on this subject his researches were attended with equal success. From the comparison of a great number of the most circumstantial and accurate

History. observations of eclipses recorded by the Chaldeans, he was enabled to determine the period of the moon's revolution relatively to the stars, to the sun, to her nodes, and to her apogee. These determinations are among the most precious relics of ancient astronomy, inasmuch as they corroborate the results of theory in one of its finest deductions—the acceleration of the mean lunar motion—and thus furnish one of the most delicate tests of the truth of Newton's law of gravitation. It was, indeed, by a comparison of the observations of Hipparchus with those of the Arabian and modern astronomers, that Dr Halley was led to the discovery of that curious and important phenomenon. Hipparchus also determined the eccentricity of the lunar orbit, and its inclination to the plane of the ecliptic; and the values which he assigned to these elements, making allowance for the evection and the inequalities of the moon's motion in latitude, are to a few minutes the same as those which are now observed. He had also an idea of the second inequality of the moon's motion, namely, the evection, and made all the necessary preparations for a discovery which was reserved for Ptolemy. He likewise approximated to the parallax of the moon, which he attempted to deduce from that of the sun, by determining the length of the frustum cut off from the cone of the terrestrial shadow by the moon when she traverses it in her eclipses. From the parallax he concluded that the greatest and least distances of the moon are respectively equal to 78 and 67 semi-diameters of the earth, and that the distance of the sun is equal to 1300 of the same semi-diameters. The first of these determinations exceeds the truth; the second falls greatly short of it, the distance of the sun being nearly equal to 24,000 terrestrial semi-diameters. It may, however, be remarked that Ptolemy, who undertook to correct Hipparchus with regard to the parallax, deviated still farther from the truth.

The apparition of a new star in the time of Hipparchus induced him to undertake the formation of a catalogue of all the stars visible above his horizon, to fix their relative positions, and mark their configurations, in order that posterity might have the means of observing any changes which might in future take place in the state of the heavens. This arduous undertaking was rewarded by the important discovery of the precession of the equinoxes, one of the fundamental elements of astronomy. By comparing his own observations with those of Aristillus and Timocharis, he found that the first point of Aries, which, in the time of these astronomers, or 150 years before, corresponded with the vernal equinox, had advanced two degrees, according to the order of the signs, or at the rate of 48 seconds a year. This determination is not very far from the truth; for, according to modern observations, the rate of the precession is about 50.1 seconds annually. His catalogue contained 1080 stars: it is generally, but erroneously, stated to have contained only 1022, after that of Ptolemy, in which the nebulous and some obscure stars are omitted. He also commenced a series of observations to furnish his successors with the means of forming a theory of the planets. Hipparchus likewise invented the planisphere, or method of representing the starry firmament on a plane surface, which afforded the means of solving the problems of spherical trigonometry in a manner often more exact and more commodious than the globe itself. He was the first who demonstrated the methods of calculating triangles, whether rectilineal or spherical; and he constructed a table of chords, from which he drew nearly the same advantages as we derive at present from the tables of sines. Geography is also indebted to him for the happy idea of fixing the position of places on

History. the earth by means of their latitudes and longitudes; and he was the first who determined the longitude by the eclipses of the moon.

These various labours and brilliant discoveries give a high idea of the industry and genius of Hipparchus. His writings have unfortunately all perished, excepting a commentary on the poem of Aratus; but the principal elements of his theories, together with a few observations, have been preserved in the *Almagest* of Ptolemy.

After the death of Hipparchus, nearly three centuries elapsed before any successor arose worthy of the name. During this long period astronomy gained no essential advancement. Some rude observations, scarcely superior to those of the Chaldeans, and a few meagre treatises, are the only monuments which exist to testify that science had not fallen into utter oblivion in an age so fertile of poets and orators. Geminus and Cleomedes wrote treatises, which have been preserved to our times; Agrippa and Menelaus are said to have observed; the Roman calendar was reformed by Julius Cæsar and the Egyptian astronomer Sosigenes; and Posidonius measured a degree, and remarked that the laws of the tides depend on the motions of the sun and moon.

Ptolemy,
A. D. 130.

Ptolemy was born at Ptolemais in Egypt, and flourished at Alexandria about the 130th year of our era, under the reigns of Adrian and Antoninus. This illustrious ornament of the Alexandrian school is entitled by his own discoveries to the high rank among astronomers which has universally been assigned to him; but the most signal service which he conferred on science was the collection and arrangement of the ancient observations. Out of these materials he formed the *Μεγάλη Συνοψις*, or *Great Composition*, a collection which exhibits a complete view of the state of astronomy in the time of Ptolemy, and which contains the germ of most of the methods in use at the present day.

The hypothesis which Ptolemy adopted for the purpose of explaining the apparent motions, was that which had been followed by Hipparchus. We have already seen that the genius of Pythagoras, soaring above the illusions of sense, had conceived the sun to be situated at the centre of the universe, and the earth to circulate, like the other planets, about the sun; and that the same opinion was entertained and supported by Aristarchus and a few other astronomers. It would seem, however, that this philosophical idea never gained much ground in antiquity, even among the learned. The vulgar prejudice respecting the immobility of the earth continued to prevail; and it had become an inveterate axiom, that all the celestial motions must be circular and uniform. Ptolemy himself, who felt in its full force the difficulty of reconciling the appearances with the notion of a uniform circular motion, adopted the common opinion without scruple as a primordial law of the universe; for, says he, this perfection belongs to the essence of celestial things, which neither admit of disorder nor irregularity. To save this chimera—the uniform circular motion—Apollonius imagined the ingenious apparatus of epicycles and deferents; and Hipparchus advanced a step farther, by placing the centre of the sun's circle at a small distance from the earth. Ptolemy adopted both hypotheses, and supposed the planet to describe an epicycle by a uniform revolution in a circle, the centre of which was carried forward uniformly in an eccentric round the earth. By means of these suppositions, and by assigning proper relations between the radii of the epicycle and deferent circle, and also between the velocity of the planet and the centre of its epicycle, he was enabled to represent with tolerable accuracy the apparent motions of the planets, and particularly the phe-

nomena of the stations and retrogradations, which formed the principal object of the researches of the ancient astronomers. The notions of Apollonius and Hipparchus were thus reduced to a systematic form, and the proportions of the eccentrics and epicycles of all the planets assigned, by Ptolemy; on which account the system has been generally ascribed to him, and obtained the name of the *Ptolemaic System* of the universe. As a first attempt to bring the celestial motions within the grasp of geometry, it does infinite honour to the genius of its inventors. It is, however, totally irreconcilable with the precision of modern observations; for it is impossible to represent on this hypothesis the variations of the distances of the planets at the same time with their apparent motions. But this difficulty could scarcely be felt by Ptolemy, inasmuch as it was impossible, before the invention of the telescope and micrometer, to form any accurate estimate of the variations of the apparent diameter of a planet, and consequently of its distance. It must be admitted, however, that the Ptolemaic hypothesis might be sufficient for the wants of practical astronomy, that is, for calculating the places of the planets and forming tables of their motions, were it not for its extreme complication. The discovery of every new irregularity in the planetary motions exacts the addition of a new epicycle; and such was the confusion resulting from this circumstance, that Alphonso X., despairing of being able to comprehend the complicated machinery, was tempted to exclaim, that if the Deity had called him to his counsels at the creation of the world, he could have given good advice. Yet, notwithstanding all its defects, the system of Ptolemy gained a complete ascendancy over the minds of mankind, and, so difficult is it to leave the beaten path, continued to be implicitly followed by every astronomer during fourteen centuries, having been only finally exploded by Kepler's discovery of the elliptic orbit of Mars.

The most important discovery which astronomy owes to Ptolemy is that of the *Evection* of the moon. Hipparchus had discovered the first lunar inequality, or the equation of the centre, which serves to correct the mean motion at the syzygies, and had also remarked the necessity of another correction for the quadratures. He even undertook a set of observations, with a view to ascertain its amount and its law; but death put a stop to his labours before he had brought them to a successful issue. Ptolemy completed the investigation, and discovered that the eccentricity of the lunar orbit is itself subject to an annual variation, depending on the motion of the line of the apsides. The variation of the position of the apsides produces an inequality of the moon's motion in her quarters, which has been technically denominated the *evection*. The equation given by Ptolemy, though of course empirical, is remarkably exact.

Ptolemy employed a very simple process for determining the moon's parallax, which was probably suggested to him by the situation of Alexandria, where he observed. He determined the latitude of a place a little to the south of that city, over the zenith of which the moon was observed to pass when her northern declination was the greatest possible. But when the moon is in the zenith, or in the same straight line with the observer and the centre of the earth, she has no parallax; consequently the obliquity of the ecliptic and the latitude of the station being known, the moon's greatest northern latitude was also determined. The next step was to observe the moon's meridian altitude fifteen days after the first observation, when her southern latitude was necessarily the greatest possible. This observation gave the *apparent* altitude of the moon, but her greatest northern and southern decli-

History. nations being supposed equal, her *true* altitude, as seen from the centre of the earth, was easily computed from the previous observation, and the difference between the true and apparent altitudes gave the amount of the parallax.

The observations of Hipparchus relative to the motion of the stars in longitude, or the regression of the equinoctial points, were confirmed by Ptolemy, although he mistook its amount, and diminished a quantity which Hipparchus had already estimated too low. According to Hipparchus, the regression is at the rate of two degrees in 150 years. Ptolemy reduced it to one degree in 90 years. This disagreement would seem to indicate an error of more than a degree in the observations, which can with difficulty be admitted, considering the accordance which subsists among the different observations cited by Ptolemy in support of his own determination. For this and some other reasons Ptolemy has been accused of altering the observations of Hipparchus, and accommodating them to his own theory; but there does not appear to be any just ground for the imputation. The error with regard to the regression probably arose from the circumstance, that Hipparchus had assigned too great a value to the length of the year, whence the motion of the sun with regard to the equinoxes would be made too slow, and the longitudes employed by Ptolemy consequently diminished.

Ptolemy has been called the *Prince* of astronomers,—a title which may perhaps be justified by the universal and long-continued prevalence of his system, but to which he has no claim from the number or value of his own observations. After a laborious and minute examination of the *Almagest*, Delambre doubts whether any thing, saving the author's declarations, is contained in that great work, from which it can be decisively inferred that Ptolemy ever observed at all. He indeed frequently makes mention of observations made by himself; but his solar tables, rate of the precession, eclipses, determination of the moon's motion and parallax, and, above all, his catalogue of stars, render it impossible to doubt that the greater part of the results which he has given as observations are merely computed from the tables of Hipparchus. It is therefore difficult to allow to Ptolemy that good faith and "astronomical probity which forms one of the most indispensable qualities of an observer." He never in any instance cites a single observation more than is just necessary for the object he has immediately in view, and consequently, by precluding all comparison of one observation with another, has deprived us of the means even of guessing at the probable amount of the errors of his solar, lunar, and planetary tables. If an astronomer, as Delambre justly remarks, were to adopt the same course at the present day, he would be certain of forfeiting all claim to confidence; but Ptolemy stood alone; he had neither judges nor rivals; he claimed admiration, and received it; and now no one condescends to calculate the few observations he has left us. (Delambre, *Astronomie Ancienne*, tom. i. Discours Préliminaire.) His catalogue contains only 1029 stars, and is therefore less extensive than that of Hipparchus, but it is exceedingly valuable on account of its details.

The name *Almagest* (*Μεγίστη*, with the Arabic prefix) was bestowed on the *Syntaxis* by the Arabians, into whose language it was translated in the ninth century. The first Latin translation was from the Arabic, and published at Venice in 1515. It abounds in Arabic words and idioms, and is very inaccurate and barbarous. The second Latin translation was made from the original Greek by George of Trebizond, and is greatly superior to the first.

History. It was published at Basle in 1541, and in 1551. The Greek text was published at the same time in 1538. Ptolemy was the author of numerous other works connected with astronomy, of which his *Geography*, in eight books, is the best known. It contains a list of all the places of which the latitudes and longitudes had at that time been determined. His treatise on *Optics* was supposed to be lost, till an imperfect Latin translation, from an Arabic version, was lately discovered in the king's library at Paris. The last book of this work contains a theory of astronomical refraction, more complete than any which existed before that of Cassini. It would seem that Ptolemy had not discovered the refraction at the time he composed the *Almagest*, no mention being made of the subject in that work. The explanation which he gives of the phenomenon is natural and satisfactory, indeed entirely conformable with that which is now universally adopted. The idea and explanation remained buried in the *Optics* till reproduced by Alhazen; but neither Ptolemy nor Alhazen attempted to estimate the amount of the refraction. His *Planisphere* and *Analemma*, in which he treats of the stereographic and orthographic projections of the sphere, show a perfect acquaintance with spherical trigonometry. In the last-mentioned work he makes use of the sines, and his constructions comprehend three of the four general theorems in modern use. Divers treatises also on music, dialling, chronology, and mechanics, attest the universality of Ptolemy's genius, and his unremitting application to the pursuits of science. Like Archimedes, he had a desire to transmit to posterity the history of his labours by a public monument. In the temple of Serapis, at Canopus, he is said to have consecrated a marble pillar, with an inscription containing the principal elements of his astronomy, such as the length of the year, the eccentricity of the solar and lunar orbits, the dimensions and forms of the epicycles of the planets, &c.

Decline of astronomy. On the death of Ptolemy astronomy ceased to be cultivated among the Greeks. The Alexandrian school subsisted indeed for some centuries after; but genuine science had fled, and its place been usurped by the vain wranglings of theologians and grammarians. During the long period of six or seven centuries, the labours of those who assumed the name of astronomers were confined to needless or trifling commentaries on the works of Hipparchus and Ptolemy, and were productive of no observations, or even remarks, having a tendency to enlarge the boundaries of the science. The genius of the Roman dominion was unfavourable to the development or exercise of the higher faculties of the human intellect; and the natural sciences, with the liberal arts, faded away under the withering influence of military despotism.

From the brief account which has now been given, it will be easily inferred that the Greeks cultivated astronomy rather as a speculative than a practical science. None of their numerous sects ever evinced any taste for observation or experiment; and hence, while geometry made great and rapid advances in their hands, physics and experimental philosophy were entirely neglected. The prevailing passion for speculation pervaded even their astronomy. They explained the doctrine of the sphere, and the apparent motions of the planets; and framed ingenious theories to account for such phenomena as came immediately under the cognizance of their senses; but if we except the observations of Hipparchus and Ptolemy, and perhaps two solstitial distances of the sun from the zenith, observed by Eratosthenes, we remark among them no observations made with instruments capable of measuring angular distances. Before Hipparchus, no mention is made of the astrolabe; and the recorded determinations do not

History. give us a very favourable idea of the accuracy of that instrument. On casting our eyes over the catalogue of Ptolemy, we scarcely ever meet with a fraction of a degree smaller than one-twelfth, that is to say, less than five minutes; whence we may infer that the astrolabe only measured twelfth parts of a degree. Occasionally, indeed, the fractions one-fourth and three-fourths occur; but these were most probably inserted by estimation. The Greeks of Alexandria committed an error of no less than 15' with regard to the altitude of the pole, one of the most essential elements to an observer; and it does not appear that they were ever able to determine the time to within a quarter of an hour. Yet notwithstanding these circumstances, which indicate that the art of observation was still in its infancy, the science of astronomy is vastly indebted to the labours and speculations of the Greeks. The complicated but ingenious hypotheses of Ptolemy prepared the way for the elliptic orbits and laws of Kepler, which, in their turn, conducted Newton to the great discovery of the law of gravitation.

Astronomy of the Arabians.

While the nations of western Europe were involved in the thickest shades of ignorance and barbarism, the torch of science was rekindled, and blazed forth with extraordinary splendour, among the Saracens. The burst of fanaticism which enabled the followers of Mahomet to carry their religion and their arms over the fairest portion of the ancient world subsided, in a great measure, after a century and a half of uninterrupted conquest, and was succeeded by a period of repose, during which they cultivated the arts of peace and civilisation with the same ardour which had characterized their achievements in arms. Under the enlightened and munificent protection of the caliphs, Bagdat became what Alexandria had been under the Ptolemies, the centre of politeness and knowledge.

The accounts which we possess of the Saracen literature are imperfect and scanty; but the first of the caliphs who appears to have encouraged the study of astronomy was Abougiatar, surnamed Almansor, or the Victorious, who reigned in the eighth century. His grandson Almamon, the seventh of the Abassides, and second son of the famous Haroun Al Raschid, who reigned at Bagdat from 813 to 833, is celebrated for the protection which he gave to learning, and the zeal with which he laboured to propagate the sciences of the Greeks among his subjects. In granting peace to the emperor Michael III., he stipulated for liberty to collect in Greece all the writings of the philosophers. These he transported into his own country, and caused to be translated into Arabic. Finding it mentioned in the geography of Ptolemy that a degree of the earth was equivalent to 500 stadia, he resolved to have this fact verified by a new measurement; and in obedience to the commands of the caliph, a company of mathematicians assembled in the spacious plain of Sinaar, where, having observed the altitude of the pole, they separated themselves into two parties, and proceeded in opposite directions along the meridian, measuring the distance they passed over till the altitude of the pole varied one degree. Being unacquainted with the nature of the instruments made use of in these geodetic operations, we cannot estimate the probable accuracy of the result; but as it agreed perfectly with the statement of Ptolemy, we have a right to infer that the measurement was executed in a very inadequate manner, and that the mathematicians of the caliph adopted the ancient determination from want of confidence in their own.

History. The *Syntax* of Ptolemy was translated into Arabic under the reign of Almamon, by Isaac Ben Honain. The translation was afterwards revised by Thabet or Thebith Ben Korah, and it was about this time that it received the appellation of *Almagest*. Astronomical observations, which, as we have had occasion to remark, had been greatly neglected by the successors of Hipparchus, formed a principal object of the attention of the Arabians. By the orders of Almamon, the obliquity of the ecliptic was observed, and found to be $23^{\circ} 33'$. According to the modern tables, the obliquity at that time was $23^{\circ} 36' 34''$, so that the error was less than that of Hipparchus and Ptolemy, in their determination of the same element. This observation supposes instruments of some accuracy. Among the astronomers whom Almamon drew to his court, we find the names of Habash of Bagdat, who composed three books of astronomical tables; Ahmed, or Mohammed Ben Cothair, better known by the name of Alfragan, or Alfranius, who, from his great expertness in computing, was styled the *calculator*. He composed an elementary treatise on astronomy, which was only an abridged extract of the works of Ptolemy; and likewise wrote on sun-dials, and gave a description of the astrolabe. The Jew Meshala, whose treatise on the elements was published at Nuremberg in 1549, also lived in the time of Almamon or Almamon.

The most celebrated of the Arabian astronomers was Albategnius, or Muhammed Ben Geber Albatani, so called from Batan, a city of Mesopotamia, where he was born. He was a prince of Syria, and resided at Aracte or Racha, in Mesopotamia; but many of his observations were made at Antioch. Having studied the *Syntax* of Ptolemy, and made himself acquainted with the methods practised by the Greek astronomers, he began to observe, and soon found that the places assigned to many of the stars in Ptolemy's tables were considerably different from their actual situations, in consequence of the error which that great astronomer had committed with regard to the precession of the equinoxes. Albategnius measured the rate of the precession with greater accuracy than had been done by Ptolemy; and he had still better success in his attempt to determine the eccentricity of the solar orbit, his value of which differs extremely little from that which results from modern observations. In assigning the length of the year, however, he fell into an error of more than two minutes; but this proceeded, as has been shown by Dr Halley, from too great confidence in the observations of Ptolemy. Albategnius also remarked that the place of the sun's apogee is not immovable, as former astronomers had supposed, but that it advances at a slow rate, according to the order of the signs,—a discovery which has been confirmed by the theory of gravitation. A new set of astronomical tables, more accurate than those of Ptolemy, likewise resulted from the indefatigable labours of Albategnius; and his observations, important in themselves, are doubly interesting on account that they form a link of connection between those of the astronomers of Alexandria and of modern Europe. The works of Albategnius were published in 1537, under the title of *De Scientia Stellarum*.

Thebith Ben Korah, another Arabian, acquired celebrity by proposing an explanation of the motions of the stars, which, under the name of the "System of Trepidation," was eagerly received by the astronomers of the middle ages, and disfigured the tables of Alphonso, and even those of Copernicus. He ascribed to the *eighth* sphere, or that of the fixed stars, two motions; one the diurnal motion, the other that of trepidation, performed in small circles round the first points of Aries and Libra, and of

History. which the radii were $4^{\circ} 18' 33''$. He therefore supposed two ecliptics, one fixed in the ninth sphere, the other movable in the eighth. According to this construction, the motion of the stars is sometimes direct and sometimes retrograde.

The Arabians have been said to be not only the cultivators but the apostles of the sciences, on account of the activity with which they propagated them among all the nations subjected to their dominion. The Fatimite caliphs, who reigned in Egypt during two centuries, rivalled their predecessors the Ptolemies in the encouragement which they gave to astronomy. Under the caliph Hakem, who reigned from 996 to 1021 of our era, Ebn Jounis acquired a splendid reputation. He constructed a set of tables, and composed a sort of celestial history, in which he has recorded numerous observations of his own and of other astronomers belonging to the same country. This work, imperfectly known through some extracts, long excited the curiosity of astronomers, as it was supposed to contain observations tending to establish the acceleration of the mean motion of the moon. A manuscript copy of it, belonging to the university of Leyden, was, in 1804, transmitted to the French Institute, and translated by Professor Caussin. It contains 28 observations of eclipses from the year 829 to 1004; seven observations of the equinoxes; one of the summer solstice; one of the obliquity of the ecliptic made at Damascus, by which the value of that element is found to be $23^{\circ} 35'$; and likewise a portion of tables of the sun and moon, with some other matter illustrative of the state of astronomy among the Arabians. The observations which regard the acceleration of the mean lunar motion are two eclipses of the sun and one of the moon, observed by Ebn Jounis, near Cairo, in the years 977, 978, and 979, and they agree with theory in confirming the existence of that phenomenon.

The Saracen conquests in Spain were attended with the same happy results as in Egypt, and science flourished in that country while the rest of Europe was involved in the darkest shades of ignorance. Arzachel is supposed to be the author of the *Toledo Tables*, constructed about the year 1180, but which, on account of the established reputation of those of Albategnius, were never in great estimation. He made some changes in the dimensions which had been assigned by Hipparchus and Ptolemy to the solar orbit, and deserves the praise of having been an exact and attentive observer. Alhazen, who flourished in the same country about the same period, contributed to the progress of astronomy by a treatise on *Optics*, in which he clearly indicated the necessity of making an allowance for the celestial refraction in astronomical observations. His treatise contained a theory of reflection and refraction, an explanation of the cause of the twilight, and of the magnitude of the horizontal moon. Averroes, a physician of Cordova, made an abridgement of the *Almagest* in the twelfth century, and Almanson found the obliquity of the ecliptic to be $23^{\circ} 33' 30''$, which proves that practical astronomy had now attained to a tolerable degree of exactness.

If we inquire what effect the labours of the Arabians and their disciples had on the progress of astronomy, we shall find that their services were confined entirely to the practical part. In point of theory they did absolutely nothing. They admitted all the hypotheses of Ptolemy without the slightest alteration, even with timid and superstitious respect, and did not advance a single step towards the discovery of the solar system. But with regard to instruments and methods of calculation, their improvements were numerous and important. They constructed instruments on a larger scale, and divided them with greater care; and,

even from the time of Almamon, we remark among them new and more exact determinations of the obliquity of the ecliptic, of the positions of some stars, of the precession, of the length of the year, and of the eccentricity of the sun's orbit. To these fundamental points they added numerous observations of eclipses and conjunctions; they industriously sought out and corrected the errors of Ptolemy's tables; they perceived the necessity of marking the instant of each phenomenon with greater care; and their determinations of the commencement and end of eclipses are in general accompanied with the altitude of a star, which afforded them the means of calculating the hour, angle, and the true time. In cases where less precision was wanted, they made use of their clepsydræ and solar dials, to the construction of which they paid particular attention. Trigonometry derived signal advantages from their constant care to facilitate the calculations of spherical astronomy. Albategnius substituted the sines for the chords,—a most important improvement, the idea of which was probably suggested to him by the *Analemma* of Ptolemy. By this happy substitution the solution of all rectangular spherical triangles was reduced to four general formulæ, of which the Greeks had the equivalent in a much less commodious form. The same astronomer also appears to have invented a very remarkable rule for the oblique-angled triangles, perfectly identical with one of the four general formulæ now in use. Ebn Jounis, and his contemporary Aboul Wefa, were acquainted with the tangents and secants, and employed them very dexterously in reducing complicated binomial expressions to a single and simpler term. They also employed subsidiary arcs and other artifices in the calculus of the sines, in order to facilitate the labour of computation. These substitutions are now common; but they remained long unknown in Europe; and 700 years after they were employed by the Arabians, we first meet with some examples of their use in the writings of Thomas Simpson.

The zeal of the Arabians for astronomical observations was communicated by them to the Persians and Tartars. About the year 1072, Omar Cheyam determined the length of the tropical year, and introduced the calendar which has ever since been used in Persia. Hologu-Ilecou-Khan, who conquered that country about the year 1264, caused an observatory to be built at Maragha, near Tauris, where he assembled the most celebrated astronomers who could be found within his dominions, and employed them in forming new astronomical tables. This work was directed by the famous Nassireddin, and brought to a conclusion in the year 1269. With the exception of some trifling corrections of the mean motions, the whole of these tables are copied from Ptolemy.

Ulugh Beigh, a Tartar prince, and grandson of the great Tamerlane, not only encouraged the study of astronomy, but was himself a diligent and successful observer. At Samarcand, the capital of his dominions, he established an academy of astronomers, and caused the most magnificent instruments to be constructed for their use. By means of a gnomon 180 feet in height, he determined the obliquity of the ecliptic to be $23^{\circ} 30' 20''$, the precession of the equinoxes at 1° in 70 years, and obtained elements for the construction of tables which have been found to be scarcely inferior in accuracy to those of Tycho Brahé. The ancient astronomy had produced only one catalogue of the fixed stars, that of Hipparchus. Ulugh Beigh has the honour of having formed a second, after an interval of sixteen centuries. This learned and munificent prince, whose virtue and talents deserved the esteem of mankind, was assassinated by his own son in the 58th year of his age.

Hologu-Ilecou-Khan, died 1269.

Ulugh Beigh, died 1449.

History.

Revival of Astronomy in Europe.

After the death of Ulugh Beigh, astronomy received no farther accessions in the east. But the seeds of knowledge had now begun to take root in a more propitious soil, and Europe, destined to carry the development of the human energies to its fullest extent, began to awake from the lethargy in which it had continued during so many ages. The first dawns of returning day appeared in Spain. In spite of the horror inspired by the Moslem religion, the Christians began to perceive and acknowledge the superiority and utility of the science of the Moors; and the schools of Cordova became the resort of all those whom curiosity, or love of knowledge, induced to seek abroad for that information which could not be obtained in their own countries. Geber, afterwards Pope Silvester II., acquired the knowledge of arithmetic from that source; and John of Halifax, better known by the name of Sacrobosco, after having studied some time in Spain, made an abridgement of the *Almagest*, which was long famous under the title of a *Treatise of the Sphere*.

Frederick II.

The emperor Frederick II. is no less celebrated for his protection of the sciences, than for the continual struggles in which he was involved with the popes. He founded the university of Naples, and caused Latin translations to be made of the works of Aristotle and the *Almagest* of Ptolemy. About the same time astronomy was zealously encouraged and cultivated by Alphonso X., king of Castile. This monarch, whose liberal mind seems to have been far superior to the age in which he lived, formed a college or lyceum at Toledo, the capital of his dominions, whither he assembled the most eminent astronomers that could be found, whether Christians, Moors, or Jews, and engaged them in the task of correcting the errors of the ancient tables. From their united labours were produced the *Alphonsine Tables*, which obtained great celebrity, and were, in some respects, superior in accuracy to any which had preceded them. They are supposed to have been chiefly the work of the Rabbi Isaac Aben Sid, surnamed Hazan, inspector of the synagogue of Toledo. They are said to have cost the king 40,000 ducats,—a sum certainly far exceeding their real value, which is confined to the correction of some epochs, and a more accurate determination of the sun's motions and the length of the year. The same century gave birth to several other individuals distinguished by their attachment to the sciences. Campanus of Nivari translated Euclid, and left a treatise on the sphere. Vitello, a native of Poland, composed a treatise on optics, in ten books; and Albert, bishop of Ratisbon, whom his contemporaries styled the *great*, was the author of some works on arithmetic, geometry, astronomy, and mechanics. But the greatest luminary of that age was Roger Bacon, a Franciscan friar, whose numerous works contain many indications of a powerful and inventive genius. He made many important discoveries in optics; but his knowledge of natural philosophy and chemistry, uncommon in those days, had nearly proved fatal to him; for he was suspected of necromancy, and thrown into a dungeon, from which he did not escape till he had satisfied his superiors and the pope that he had never held unlawful intercourse with the devil. He composed a work on the utility of astrology, the places of the stars, and the aspects of the moon; and he had the merit of perceiving the necessity of reforming the calendar.

Roger Bacon, born 1214, died 1294.

Purbach, born 1423, died 1461.

The fourteenth century produced no astronomer from whose labours the science gained any accessions. George Purbach, or Beurbach, so named from a small town in Austria, where he was born in 1423, obtained great celebrity as a professor. He studied at Vienna, and after

giving proofs of distinguished talents, he travelled into Italy, where he was favourably received by the cardinal of Cusa, who himself cultivated astronomy. On his return to Vienna he undertook a translation of the *Almagest*; and although ignorant both of Greek and Arabic, his perfect acquaintance with the subject enabled him to correct many errors which had been introduced through the carelessness or ignorance of former translators. He published a table of sines for every ten minutes to a radius of 6,000,000 parts, which was afterwards extended by his scholar Regiomontanus to every minute of the quadrant. The most celebrated of his works is his *Theorica Novæ Planetarum*, which was published in 1460. He constructed a celestial globe, on which was represented the motion of the stars in longitude from the time of Ptolemy to the year 1450. He also measured the obliquity of the ecliptic, and is considered as the inventor of decimal arithmetic. He died in 1461, having only reached his 38th year, with the reputation of being, at that time, the first astronomer in Europe.

Purbach had the good fortune to form a disciple who executed many of the plans which had been interrupted by his premature death. This was the celebrated John Muller of Königsberg, better known by the name of Regiomontanus. Attracted in his youth to Vienna by the great reputation of Purbach, he continued to study there during ten years, and on the death of his master repaired to Rome for the purpose of acquiring the Greek language, and of making himself, through it, acquainted with the *Almagest*. At Rome he continued his observations, and translated into Latin the works of Ptolemy, the *Conics* of Apollonius, and some other treatises of ancient science. In 1471 he retired to Nuremberg, where, with the aid of Bernard Walther, a wealthy burgess, he founded an observatory, and furnished it with excellent instruments, principally of his own invention, by means of which he was enabled to detect many errors in the ancient tables. On the invitation of Pope Sixtus IV., who wished to reform the calendar, he again repaired to Rome; but after a few months' abode there he died suddenly, according to some accounts, of the plague, according to others, through the effects of poison administered to him by the sons of George of Trebizond, who adopted this execrable method of revenging the exposure which he had made of their father's errors in the translation of the *Almagest*. Regiomontanus was a learned and skilful man, but the great expectations which his early labours gave of future services to astronomy were disappointed by his untimely death. He paid great attention to trigonometrical calculation; and, although he did not reach the point which had been attained by the Arabians, he had the merit of introducing some useful theorems which till then were entirely unknown in Europe. His genius, however, did not enable him to rise above the prejudices of his age, for he was an astrologer as well as an astronomer, and is said to have most lamented the errors of the Alphonsine Tables on account of the uncertainty which they occasioned in the calculation of genitures or horoscopes.

After the death of Regiomontanus, Walther continued to observe at Nuremberg during thirty years. His observations were collected by order of the senate of Nuremberg, and published by Schöner in 1544, a second time by Snellius, and, lastly, along with those of Tycho Brahé. In 1484 Walther began to make use of clocks, then a recent invention, to measure time in celestial observations. He was also the first who employed the planet Venus as a term of comparison for determining the longitudes of the stars.

Nuremberg had the honour of producing another astro-

Walther, born 1430, died 1504.

History. Werner born 18. nomer of some celebrity. John Werner was the first who explained the method which was afterwards brought into general use by Maskelyne, of finding the longitude at sea, by observing the distance between a fixed star and the moon. He published some mathematical and geographical treatises, and made a number of observations to determine the obliquity of the ecliptic and the precession of the equinoxes.

Overthrow of the Ptolemaic system. We are now come down to a period in the history of astronomy when the science was destined to undergo a total renovation, and the system which had been so laboriously established by Ptolemy, and blindly followed as an article of religious belief by Arabs, Persians, Tartars, and Europeans, during so many centuries, was about to be exploded for ever. In proportion as the observations became more numerous and accurate, the difficulty of representing them by the Ptolemaic system became greater; and astronomers were obliged to have recourse to the most violent and improbable suppositions in order to explain the phenomena, and, in the language of Ptolemy, *save the appearances*. We have mentioned that Pythagoras and his disciples entertained an idea very different from that which commonly prevailed, and supposed the sun to be the immovable centre of the celestial motions. It appears, however, from Aristotle, that this opinion was not founded on any analysis of the phenomena, but on certain metaphysical notions respecting the comparative dignity of the several elements. For example, fire, being a nobler substance than earth, ought to occupy the centre or place of honour. But such arguments could have little weight except in the schools, and accordingly were rejected by Ptolemy as too absurd to require a serious refutation. In order to give any probability to the Pythagorean doctrine, it was necessary to explain the succession of the seasons and the precession of the equinoxes on the hypothesis of the annual revolution of the earth about the sun; to show how the unequal motions of the planets in concentric orbits would give rise to the phenomena of the stations and retrogradations; to account, in short, for all the appearances, and point out their coherence and mutual connection. All this was effected by Copernicus, who had thereby the glory of first making known the true system of the universe, and of leading the way in that career of astronomical discovery in which the genius of the human race has gained its noblest trophies.

Copernicus, born 1472, died 1543. Nicholas Copernicus was born at Thorn, a city of Prussia, on the confines of Poland, according to Junctinus on the 19th of January 1472, and according to others on the 19th February 1473. From his earliest years he displayed a great fondness and aptitude for mathematical studies, and pursued them with corresponding success at the university of Cracow. Stimulated by the desire of acquiring a reputation equal to that of Regiomontanus, he set out for Italy at the age of 23 years, in order to study astronomy at Bologna under the celebrated Dominic Maria. He afterwards removed to Rome, where he employed himself in studying and teaching the mathematics, and where he made several astronomical observations about the year 1500. On his return to his native country he was made a canon of Ermeland by his uncle the bishop of Worms, and took up his residence at Frauenberg, a small Prussian town near the mouth of the Vistula, where he passed 36 years of his life in observing the heavens and meditating on the system of the world. In this retirement he composed his famous work entitled *Astronomia Restaurata, sive de Revolutionibus Orbium Caelestium*, in which he explained the celestial motions in a manner as simple and connected as the system of Ptolemy

History. was complicated and incoherent. The system which Copernicus adopted in this work is now so familiar to every one, that it is almost unnecessary to describe it. The heaven, composed of stars perfectly at rest, occupies the remotest bounds of space, then the orbit of Saturn, next Jupiter, Mars, the Earth accompanied by its moon, Venus, Mercury, and, lastly, the Sun immovable at the centre. By this arrangement the stations and retrogradations of the planets became simple mathematical corollaries, following from the differences of the radii of their orbits and their unequal motions. The diurnal rotation of the earth explained more simply and rationally the apparent daily revolution of the heavens; and the precession of the equinoxes was referred to a small variation in the inclination of the earth's axis to the plane of the ecliptic. But the simplicity of the system, and its consequent probability, were the only arguments which Copernicus was able to bring forward in proof of its reality. The motion of the earth can indeed never be made an object of sense; but after Richer's discovery of the diminution of gravity towards the equator, it was impossible to doubt longer of the existence of its rotatory motion; and when Roemer had measured the velocity of light, and Bradley observed the phenomena of the aberration, the evidences of its annual revolution were rendered equally convincing. Great, however, as were the merits of Copernicus, it must be acknowledged that he left his system in a very imperfect state. After the example of the ancients, he assumed as an axiom the uniform circular motion of the planets; and as the only motions which are observed are in a state of incessant variation, he was obliged, in order to save the inequalities, to suppose a different centre to each of his orbits. The sun was placed *within* the orbit of each of the planets, but not in the centre of any of them, consequently he had no other office to perform than to distribute light and heat; and, excluded from any influence on the system, he became as it were a stranger to all the motions. Yet notwithstanding these and other imperfections, the establishment of the doctrine of the earth's motion, with an evidence which dissipated the illusions of sense, was a great step towards the true knowledge of the planetary system; and when we consider the ignorance and prejudices of the age, and that Copernicus was moreover a priest, we cannot hesitate to admit his claim to a high rank among philosophers. But whether the actual services which he rendered to astronomy are commensurate with the great fame he has obtained, may admit of doubt. He revived an ancient opinion opposed to the prejudices and religious dogmas of his times, and fortified it with new and strong, though not absolutely convincing, proofs. It seldom happens, however, with regard to those sciences which ultimately appeal to experience, that general reasoning, even of the soundest kind, tends much to their real advancement; and there is little reason for thinking that astronomy would have been less perfect, or that any discoveries since made in it would have been retarded a single day, even if Copernicus had never lived. His great merit, like that of Lord Bacon, consists in the sound views which he took of nature, and in advancing so far before the general attainments of his age.

Fearing the opposition which was likely to arise from religious bigotry to opinions so much at variance with vulgar prejudice, Copernicus long delayed the publication of his great work; and it was only at the urgent request of his friends that he at last allowed it to be printed. He is said to have received the last sheet of it only on the day of his death. He was buried in the cathedral of Frauenberg, and his only epitaph consisted of some spheres cut out in relief on his tombstone.

History. The ideas of Copernicus soon spread over Germany, where astronomy was at that time diligently cultivated; but they do not seem to have met with general favour before the commencement of the seventeenth century. The art of observing was, however, gradually receiving improvement; instruments were constructed on better principles, and more accurately divided; and the methods of computation were rendered much less laborious. Nonius, or Nunez, a Portuguese, invented the ingenious method of subdividing the small divisions of instruments which still retains his name; Reinhold extended the table of tangents of Regiomontanus to every minute of the quadrant, reformed the tables of Copernicus, and composed many works of practical utility; but of the immediate successors of Copernicus, no one deserves to be more honourably mentioned than William IV., landgrave of Hesse. This prince built a magnificent observatory on the top of his palace at Cassel, which he furnished with excellent instruments of copper, and is said to have calculated himself the positions of no less than 400 stars. He was aided in the labours of the observatory by some astronomers of great merit whom his liberality drew to his court; among others, by Rothman, and Justus Byrgius, a distinguished artist, to whom Kepler has ascribed some idea of the logarithms.

William
IV., died
1592.

Tycho
Brahe,
born 1546,
died 1601.

Tycho Brahe, one of the best and most indefatigable observers of whom practical astronomy can boast, was born at Knudstorp, in Scania, the 13th of December 1546. His family was one of the most ancient and noble in Denmark; and his father, probably thinking that illustrious birth superseded the necessity of education, refused his consent to have his son instructed in Latin. Through the kindness of a maternal uncle, however, he was rescued from the state of barbarous ignorance to which he had been doomed by his parent; and, after having received the requisite preliminary instruction, he was sent to the university of Leipsic to study jurisprudence and scholastic philosophy. The tastes of the future astronomer were first excited by an eclipse of the sun which happened in 1560. Struck with astonishment at the accuracy of the prediction, he conceived a vehement desire to become acquainted with the principles of so certain a science, and exerted his utmost ingenuity to elude the obstacles which were interposed by his parents and governor to prevent him from acquiring the elementary notions of mathematics and astronomy. By placing the hinge of a common compass near his eye, he contrived to guess at the distances of the planets from the stars, and by this means, according to his own account, detected several errors in the Ephemerides of Stadius. By his persevering efforts he at last obtained the consent of his family to study according to his own inclinations; and from that moment he divided his time between the observation of the heavens, and chemical experiments. He visited the different cities of Germany where he hoped to meet with astronomers and skilful mechanicians, and was received with flattering attention by the landgrave of Hesse-Cassel, with whom he contracted an intimate friendship. On his return to Denmark he obtained from Frederick II. a grant of the small island of Huen, in the strait of Sunda, together with a pension and some presents, by means of which, and an expenditure of 100,000 crowns of his own patrimony, he was enabled to build the castle of Uraniburg, and procure a magnificent collection of the largest and most accurate instruments which could then be constructed. In this celebrated retreat he passed twenty-five years, actively employed in making observations, and attracting by his discoveries the attention of the learned throughout Europe. On the death of his protector Fre-

derick he fell under the displeasure of the government, and a storm of persecution was raised against him, from causes which he has not explained, by a minister named Walckendorp, who, on this account, has been devoted by Lalande to the infamy and execration of all ages. He was deprived of his pension, compelled to leave the castle of Uraniburg, and to banish himself from Denmark. He retired first to Wandesburg, near Hamburg; he afterwards sought an asylum in Bohemia, and ultimately settled at Prague under the protection of the emperor Rudolph II. Here he resumed his observations, assisted by the illustrious Kepler and Longomontanus. The causes of his exile are involved in mystery; but to whatever it was owing, it turned out fortunate for the progress of astronomy. Had he remained in his island, his observations would not probably have fallen into the hands of Kepler, and the discovery of the laws of the planetary motions might have been deferred to another age. He died at Prague on the 24th of October 1601.

As an indefatigable and skilful observer, Tycho is justly considered as far superior to any astronomer who had preceded him since the revival of the science in Europe. His ample fortune gave him the means of procuring the best instruments which the age could produce; and by his ingenuity and persevering application, he was admirably qualified to employ them to the best advantage. He computed the first table of refractions, and if it extended only to 45°, the reason was, that the effects of refraction, at a higher altitude, were altogether insensible to his instruments. His solar tables were brought to so great a degree of exactness, that he affirms he could never detect an error in them exceeding a quarter of a minute; but there is reason to suspect some exaggeration in this statement, particularly as Cassini, a century after, with much better means, could scarcely answer for errors of a whole minute. He contributed greatly to the improvement of the lunar tables, and detected a considerable inequality in the moon's motion in longitude, to which he gave the name of the *Variation*, by which it has ever since been distinguished. He also discovered an equation in latitude similar to the evection which had been observed by Hipparchus, and fixed its amount with great accuracy. He remarked the fourth inequality of the moon in longitude, although he failed in his attempt to ascertain its amount, or assign its law. He represented the inequalities of the motions of the nodes, and in the inclination of the lunar orbit, by the motion of the pole of that orbit in a small circle round the pole of the ecliptic. He demonstrated that the region of the comets is far beyond the orbit of the moon, and determined the relative and absolute positions of 777 fixed stars with a scrupulous attention, which gave his catalogue an immense superiority over those of Hipparchus and Ulugh Beigh; and he left to his successors a regular series of observations on the planets, amassed for the purpose of establishing the truth of his own system, but of which Kepler made a better use by employing them to establish the system of Copernicus.

These are some of the important benefits which resulted to astronomy from the labours of Tycho. As a philosopher he ranks low. Alchemy and judicial astrology, in the reveries of which he was a firm believer, engrossed as much of his attention as astronomy. Yet his errors, or rather weaknesses, ought to be viewed with indulgence. He was seated, to use the simile of Bailly, on the confines of two ages; partaking of the darkness which preceded, and the light which came after him. He rejected the simple system of Copernicus, and, whether from participating in the religious scruples of his age, or from the

History.

History. ambition of appearing as the author of a new system, he restored to the earth its immobility, and placed it in the centre of the motions of the sun and moon. The Tycho-nic system was an unsuccessful attempt to reconcile the incongruous hypotheses of Ptolemy and Copernicus. It never enjoyed any real estimation; and its followers were only found among those who dreaded the anathemas of the church, or who, belonging to some university or religious corporation, were deprived of the liberty of expressing their real opinions.

Longomontanus, born 1526, died 1607. Tycho was assisted in his observations at Huen, during eight years, by Longomontanus, who afterwards became professor of the higher mathematics at Copenhagen. This astronomer composed a large work, entitled *Astronomia Danica*, in which he deduced the elements of the different theories from the observations made at Uranibourg, and gave formulæ for computing the planetary motions, according to the three systems of Ptolemy, Copernicus, and Tycho.

Kepler, born 1571, died 1630. The great mass of accurate observations accumulated by Tycho furnished the materials out of which his disciple Kepler may be said to have constructed the edifice of the world. This great man, the true founder of modern astronomy, was born at Wiel, in the kingdom of Wurtemberg, on the 27th of December 1571. He studied philosophy at Tubingen, and was instructed in mathematics and astronomy by Mæstlin, whose name deserves a place in the history of science, on account of his having been one of the first who had the courage to adopt and to teach the system of Copernicus. The philosophical mind of Kepler, disgusted with the improbabilities and absurdities of the ancient system, received with transport the novel doctrines explained by Mæstlin. The appointment of mathematician to the emperor, which he procured on the death of Stadius, confirmed him in the resolution which he had taken to devote himself to astronomical pursuits; and the energy of his character enabled him in a very short time to make himself thoroughly master of the different hypotheses and principal discoveries which had been made prior to his time. In the year 1596 he published a *Prodromus* of Dissertations on the properties and causes of the celestial orbits, which procured him the friendship of Tycho, and an invitation to take part in the observations and researches of that great astronomer at Prague. On the death of Tycho, which happened soon after, Kepler obtained possession of his invaluable collection of observations, and was charged with the task of completing and publishing the *Rudolphine Tables*.

During his short residence with Tycho, Kepler learned to check the fanciful suggestions of his brilliant imagination, and to draw his conclusions from observations alone, by rigorous and patient induction. The observations of the Danish astronomer had furnished him with the means of establishing with certainty the truth or inaccuracy of the various hypotheses which he successively imagined; and the diligence with which he laboured in comparing and calculating these observations during 20 years, was finally rewarded by some of the most important discoveries which had yet been made in astronomy. Deceived by an opinion which had been adopted by Copernicus, and had never been called in question by the ancients, that all the celestial motions are performed in circles, he long fruitlessly endeavoured to represent, by that hypothesis, the irregular motions of Mars; and after having computed with incredible labour the observations of seven oppositions of that planet, he at length succeeded in breaking down the barrier which had so long obstructed the progress of knowledge, and found that the motions could only be

History. accurately represented by supposing the planet to move in an ellipse, having the sun in one of its foci. Having arrived at this important result, he next proceeded to consider the angular motion of the planet, and finding that it was not uniform in respect of any point situated within the orbit, he concluded that the uniform motion, till then universally received as an axiom, was a vain chimera, which had no existence in nature. He perceived, however, that the areas described by the radius vector of the planet, at its greatest and least distances, were equal in equal times; and subsequent observations enabled him to demonstrate that this equality extended to every point of the orbit. It was therefore discovered that Mars moves in an elliptic orbit, of which the sun occupies a focus, and in such a manner, that the area described by a line drawn from the centre of the planet to that of the sun is always proportional to the time of description. The same conclusions he found to be true in respect of the orbit of the earth; and therefore he could no longer hesitate to extend them by analogy to the other planets. These are two of the three general principles which are known by the name of the *Laws of Kepler*.

It was some years later before Kepler arrived at the knowledge of the analogy which subsists between the distances of the several planets from the sun, and the periods in which they complete their revolutions. To the discovery of this analogy he attached the greatest importance, and regarded all his other labours as incomplete without it. After having imagined numberless hypotheses, it at last occurred to him to compare the different powers of the numbers which express the distances and times of revolutions; and he found, to his infinite satisfaction, that the squares of the periodic times of the planets are always in the same proportion as the cubes of their mean distances from the sun. This is the third law of Kepler. He demonstrated it to be true of all the planets then known. It has been found to be equally true in regard to those which have been since discovered, and likewise to prevail in the systems of the satellites of Jupiter and Saturn. It is indeed, as can be shown mathematically, a necessary consequence of the law of gravitation, directly as the masses, and inversely as the squares of the distances.

By these brilliant discoveries, the solar system was reduced to that degree of beautiful simplicity which had been conceived by Copernicus, but from which that great astronomer had found himself constrained to depart. The sun could not occupy the common centre of the circular orbits, but his place is in the common focus of the elliptic orbits of all the planets; and it is to this focus that every motion is to be referred, and from which every distance is to be measured. The discovery of the elliptic motion, of the proportionality of the areas to the times, and the method of dividing an ellipse, by straight lines drawn from the focus to the periphery, into segments having a given ratio, formed the solution of a problem which had been the constant object of the labours of all astronomers from Ptolemy to Tycho, namely, to assign the place of a planet at any instant of time whatever. The tables which he computed for the elliptic motions form the model of those in present use. Some additions have been made in consequence of the perturbations, which the geometry of Kepler was inadequate to estimate, and which were only partially detected by the genius of Newton. It has been considered matter of surprise that Kepler did not think of extending the laws of the elliptic motion to the comets. Prepossessed with the idea that they never return after their passage to the sun, he imagined that it would only be a waste of time to attempt the calculation of the orbits of bodies which had so transitory an existence. He supposed

History. the tail to be produced by the action of the solar rays, which, in traversing the body of the comet, continually carry off the most subtile particles, so that the whole mass must be ultimately annihilated by the successive detachment of the particles. He therefore neglected to study their motions, and left to others a share of the glory resulting from the discovery of the true paths of the celestial bodies.

The observations of eclipses had formed the principal object of the earliest astronomers, but it was Kepler who first showed the practical advantages which may be derived from them, by giving an example of the method of calculating a difference of meridians from an eclipse of the sun. The method extends to occultations of the stars, and is deservedly considered as the best we possess for determining geographical longitudes and correcting the tables. He composed a work on optics, replete with new and interesting views, and gave the first idea of the telescope with two convex glasses, which has since been advantageously substituted for that of Galileo. Prompt to seize every happy idea of his contemporaries, he perceived with delight the advantages which practical astronomy would derive from the new invention of the logarithms, and he immediately constructed a table, from which the logarithms of the natural numbers, sines, and tangents could be taken at once.

Kepler was not merely an observer and calculator; he inquired with great diligence into the physical causes of every phenomenon, and made a near approach to the discovery of that great principle which maintains and regulates the planetary motions. He possessed some very sound and accurate notions of the nature of gravity, but unfortunately conceived it to diminish simply in proportion to the distance, although he had demonstrated that the intensity of light is reciprocally proportional to the surface over which it is spread, or inversely as the square of the distance from the luminous body. In his famous work *De Stella Martis*, which contains the discovery of the laws of the planetary motions, he distinctly states that gravity is a corporeal affection, reciprocal between two bodies of the same kind, which tends, like the action of the magnet, to bring them together, so that when the earth attracts a stone, the stone at the same time attracts the earth, but by a force feebler in proportion as it contains a smaller quantity of matter. Further, if the moon and the earth were not retained in their respective orbits by an animal or other equipollent force, the earth would mount towards the moon one fifty-fourth part of the interval which separates them, and the moon would descend the fifty-three remaining parts, supposing each to have the same density. He likewise very clearly explains the cause of the tides in the following passage. "If the earth ceased to attract its waters, the whole sea would mount up and unite itself with the moon. The sphere of the attracting force of the moon extends even to the earth, and draws the waters towards the torrid zone, so that they rise to the point which has the moon in the zenith." It is not difficult to imagine how much these views must have contributed to the immortal discovery of Newton.

It is afflicting to consider how frequently the just rewards of true merit are usurped by charlatanism and pretension. While the fire-eaters and astrologers of Rudolph were basking in the sunshine of imperial favour, Kepler, from whose labours the sciences derived the most signal benefits, passed his life in extreme indigence. Born without fortune, the only revenue he possessed, and out of which he had to maintain a numerous family, arose from the precarious produce of his writings, and his pension of mathematician to the emperor,—a pension which, owing to the calamities of the times, was seldom duly paid.

On this account he was obliged to prefer frequent solicitations, and undertake long journeys, whereby he lost his time, always precious to genius, and exhausted his mind in anxiety. He died on the 15th of November 1630, at Ratisbon, whither he had gone to solicit the arrears that were due to him. In the present century a marble monument has been erected to his memory by an enlightened prince, Charles of Alberg. It contains his bust and the ellipse of Mars; a monument more glorious and more imperishable than brass or marble.

Contemporary with Kepler was the illustrious Galileo, *Galileo*, whose discoveries, being of a more popular nature, and far more striking and intelligible to the generality of mankind, had a much greater immediate effect on the opinions of the age, and in hastening the revolution which was soon about to change the whole face of physics and astronomy. Galileo-Galilei, a Florentine patrician, was born at Florence in the year 1564. He passed his youth at Venice, where he continued till he was appointed to a professor's chair at Padua. After a residence of eighteen years in that city, he was induced to remove to Pisa by Cosmo II., who assigned him a pension, and conferred on him the title of his first mathematician. While residing at Venice, he heard it reported that Metius, a Dutch optician, had discovered a certain combination of lenses, by means of which distant objects were approximated to the sight. This vague and scanty intelligence sufficed to excite the curiosity of Galileo, who immediately set about inquiring into the means whereby such an effect could be produced. His researches were attended with prompt success, and on the following day he had a telescope which magnified about three times. It was formed by the combination of two lenses, a plano-convex and plano-concave, fitted in a leaden tube. In a second trial he obtained one which magnified seven or eight times; and subsequent essays enabled him to increase the magnifying power to 32 times. On directing his telescope to the moon, he perceived numerous inequalities on her surface, the diversified appearances of which led him to conclude almost with certainty that the moon is an opaque body similar to the earth, and reflecting the light of the sun unequally, in consequence of her superficial asperities. The planet Venus exhibited phases perfectly similar to those of the moon. These phases had been formerly announced by Copernicus as a necessary consequence of his system; and the actual discovery of their existence made it impossible to doubt of the revolution of Venus round the sun. He detected the four satellites or moons of Jupiter, and, in honour of his patron, gave them the name of the *Medicean Stars*. The discovery of these little bodies circulating round the huge orb of Jupiter afforded him a strong analogical proof of the annual revolution of the earth, accompanied by its moon. He perceived spots on the disk of the sun, from the motions of which he concluded the rotation of that body about its axis in the space of 27 days. The singular appearances of Saturn were beheld by him with no less pleasure than astonishment. His telescope was not sufficiently powerful to separate the ring from the body of the planet; and to explain the appearances he supposed Saturn to be composed of three stars almost in contact with one another. These discoveries proved that the substances of the celestial bodies are similar to that of the earth, and demolished the Aristotelian doctrine of their divine essence and incorruptible nature. They enlarged the ideas of mankind respecting the planetary system, and furnished the most convincing arguments in favour of the doctrines of Copernicus.

The discoveries of Galileo excited the envy of his

History. contemporaries, and stirred up against him a persecution which embittered the last days of his life. The motion of the earth, which he had proved so triumphantly, was considered contrary to many express declarations of Scripture; it was also considered as a heresy in the schools, where the doctrines of Aristotle were followed with implicit submission. In defending the Copernican system, Galileo had incurred the bitterest resentment, both of theologians and peripatetics. His great reputation, his title of professor and first mathematician, gave them reason to dread that the new doctrines, recommended by such an advocate, would spread too rapidly, and finally overthrow the altars of Aristotle. They therefore combined to check their progress, and to procure the ruin of Galileo by injurious representatives to the Grand Duke and the court of Rome. Soon after his first telescopic discoveries he was cited to appear before the Inquisition, and a promise extorted from him that he would never, either by word or writing, support the opinion of the motion of the earth. But in a great mind the love of truth is the most imperious of all passions, and cannot be restrained by the frowns of despotism, or the persecution of a fanatical tribunal. The evidences of the motion of the earth burst forth from every point of the heavens; and Galileo, in his celebrated *Dialogues* on the system of the world, exposed them in so clear and forcible a manner, that, although he appeared to put them forth for the purpose of refuting them, it was not difficult to perceive that he regarded them as complete and indubitable. For this relapse into heresy he was again brought before the tribunal of the Inquisition, and, in the seventieth year of his age, condemned formally to retract and abjure the doctrine of the earth's motion, and to be imprisoned during the pleasure of the Inquisition. This scandalous proceeding has called forth the indignant reprobation of every lover of truth and freedom. "What a spectacle," exclaims Bailly, "an old man, whose hairs were blanched with study, watchings, and benefits to mankind, on his knees before the sacred Scriptures, abjuring the truth in the eyes of Italy, which he had enlightened, in opposition to the testimony of his conscience, and in spite of the manifestations given by nature through all her works."

The sentence passed on Galileo was not inflicted with great severity. At the end of a year the Grand Duke had the influence to procure his release from prison; but he was prohibited from returning to Florence, and obliged to confine himself to the Tuscan territory. He retired to the village of Arcetri, where he resumed his observations, and shortly afterwards discovered the libration of the moon. The satellites of Jupiter continued also to engage his attention, and he commenced a table of their motions, and pointed out the method of determining the longitude by means of their eclipses. The states of Holland, aware of the great benefit of his researches to commerce and navigation, sent two astronomers, Hortensius and Blaeu, to present him with a gold chain, and encourage him to persevere in his useful labours. A short time after receiving this honourable mark of esteem from a foreign country, Galileo suddenly became blind; and the task of forming the tables of the satellites was reserved for Cassini. He survived this misfortune only a few years, and expired in 1642, in the seventy-eighth year of his age.

Science is indebted to Galileo for two other discoveries of a different kind, less brilliant perhaps, but of far greater importance than those which we have yet enumerated. These are the isochronism of the vibrations of the pendulum, and the law of the acceleration of falling bodies. His telescopic discoveries could not have remained long unknown; in fact, with the exception of those of the phases

of Venus, and of the triple form of Saturn, they were all History. fiercely disputed, even during his own lifetime. It is now universally admitted that he was the first who discovered the satellites of Jupiter, and the spots of the sun; but the very circumstance of other claimants to these discoveries having arisen, proves that they were within the reach of ordinary attention. No one ever thought of disputing with Kepler the discovery of the laws of the planetary motions. Those of Galileo required only eyes, and may be regarded as following of course from the discovery of the telescope; but his persecution, his condemnation, and his being compelled to retract and abjure a doctrine of which he had given the physical proof, inspire a hallowed interest in his history, and contributed much to the great reputation which he acquired throughout Europe.

While astronomy was making these rapid advances in the hands of Kepler and Galileo, an event occurred in Scotland which contributed, though less directly, no less powerfully, to the acceleration of its progress. This was the invention of the logarithms by Lord Napier, baron of Merchiston; "an admirable artifice," says Laplace, "which, by reducing to a few days the labour of many months, doubles the life of the astronomer, and spares him the errors and disgust inseparable from long calculations; an invention of which the human mind has the more reason to be proud, inasmuch as it was derived exclusively from its own resources." It may be added, that without this, or some equivalent artifice, the computations rendered necessary by more correct observations would far exceed the limits of human patience or industry, and astronomy could never have acquired that precision and accuracy by which it is now distinguished above all the other branches of human knowledge.

The same epoch presents to us a great number of excellent observers, who, although they did not produce any revolution in the state of astronomy, still rendered it useful service. Scheiner is celebrated for his observations on the solar spots, and his disputes with Galileo. John Bayer of Augsburg published a description of the constellations, accompanied by maps, in which the stars are marked by a Greek letter; a simple idea, which has been universally adopted. Lansberg, a Flemish mathematician, published in 1632 a set of astronomical tables, which, though filled with inaccuracies, rendered good service to science by apprising Horrox of the transit of Venus over the sun's disk, which that young astronomer and his friend Crabtree had the satisfaction of observing on the 24th of November 1639. They were the first who ever witnessed that interesting but rare phenomenon. Snellius is celebrated for his measure of the earth. Gassendi, who had the merit, along with Descartes, of hastening the downfall of the Aristotelian philosophy in France, made some useful observations, particularly one of a transit of Mercury in 1631. His works, which fill six folio volumes, abound with curious and useful researches. Riccioli, a Jesuit, born at Ferrara in 1598, contributed to the progress of astronomy, not so much by his own discoveries, as by collecting and rendering an account of those of others. He rejected the system of Copernicus, and was more zealous in maintaining the doctrines of the church than in investigating nature; but his works form a vast repository of useful information. His *Novum Almagestum* is a collection of the observations, opinions, and physical explanations of the phenomena, together with all the methods of computation then known. He was assisted in his labours by Grimaldi, who discovered the inflection of light, and gave the names to the principal spots of the moon which are now used by astronomers.

History.
Hevelius,
born 1611,
died 1687.

The most accurate observations that were ever made prior to the adaptation of the telescope to astronomical instruments were those of Hevelius, a rich citizen of Dantzic, who devoted his life and a large fortune to the service of astronomy. Having fitted up an observatory, and furnished it with the best instruments which could be procured, he commenced a course of observations, which he followed assiduously upwards of forty years. In his *Selenographia* he has given an accurate description of the face and spots of the moon, accompanied with excellent delineations of her appearance in her different phases and librations. The idea of making drawings of the different phases of the moon had previously occurred to Gassendi and Peiresc, but they had not been able to execute the project; indeed the difficulty attending it was such, that it occupied Hevelius, who was an excellent draughtsman, as well as observer, during a great number of years. Hevelius made an immense number of researches on comets; and finding that the observations could not be represented by rectilinear or circular orbits, he supposed them to move in parabolas. During a temporary absence from Dantzic, this indefatigable astronomer had the misfortune to lose, in a great fire which occurred in the city, his observatory, instruments, manuscripts, and almost the entire edition of the second volume of his *Machina Cœlestis*, which contained the results of his long labours and numerous observations. He was now in his old age, but his zeal did not give way under the terrible calamity. He patiently recommenced all his calculations, reconstructed tables of the sun, and prepared for publication his *Firmamentum Sobiescianum*, or celestial chart, which did not appear till after his death. Towards the latter part of his life, the use of telescopic sights began to be generally adopted. Hevelius, however, resisted the innovation, and continued to employ plain sights. This preference given to the ancient method by so skilful an observer induced Dr Halley to visit him at Dantzic, for the purpose of ascertaining, by a comparison of observations made at the same time and place, which of the two methods gave the most correct results. Dr Halley observed with the telescope, and Hevelius with his own instruments; but such was the dexterity he had acquired through long practice, that the difference of their observations seldom amounted to more than a few seconds, and in no case to so much as a minute. Notwithstanding this agreement, it is to be regretted that Hevelius did not adopt the new method; for, on account of the greater precision given to instruments by the use of the telescope, his observations, which were made without it, cannot now be admitted in the construction of tables, and consequently are for the most part useless to astronomy.

Huygens,
born 1629,
died 1695.

Few individuals have rendered more important services to science than Huygens. Born at the Hague in 1629, he studied geometry under Schooten, the commentator of Descartes, and gave early proofs of proficiency in that science by a treatise on the quadrature of the conic sections. Having passed into France, he studied law at the university of Angers; but his principal attention was directed to the physical sciences, particularly to optics. He employed himself in grinding and polishing lenses; and constructed a telescope of ten feet, with which he discovered one of the satellites of Saturn. His application of the pendulum to clocks deserves to be considered as one of the best gifts which genius has ever conferred on science. He seems to have conceived the idea of this application in 1656; and he presented the first description of the pendulum clock to the states of Holland in 1657. He endeavoured to make this invention subservient to the problem of the longitudes; and if his efforts were not attend-

ed with the desired success, it may be said, that without another invention, in which also he had a principal share, that of the spiral spring, the object would never have been accomplished so nearly as it was a hundred years later. By means of his excellent telescopes he discovered that the extraordinary appearance exhibited by Saturn was occasioned by a ring surrounding the body of the planet, and inclined to the ecliptic in an angle which he estimated at 21° . He published his observations on this planet in a work entitled *Systema Saturnium*, which still shows some traces of that species of reasoning from final causes which so greatly disfigures the writings of Kepler. For example, on discovering the satellite, he conceived that as the number of satellites now equalled the number of planets, it was in vain to look for more, the equality being necessary to the harmony of the system. He lived, however, to witness the discovery of four more satellites belonging to the same planet. Huygens was invited to settle in France by Colbert, the patriotic minister of Louis XIV., who assigned him a pension and a seat in the academy of sciences. He continued in that country till the revocation of the edict of Nantz in 1681, when he resigned his pension and retired to Holland. After this he contributed several papers to the *Philosophical Transactions*, and in 1690 published a treatise on light and gravitation. Geometry, mechanics, and optics, are indebted to the genius of Huygens for many important discoveries. His theorems on central forces, his researches on the doctrine of probabilities and continued fractions, and his theory of involutes and evolutes, raise him to the highest rank among the mathematicians of his age. He died on the 8th of June 1695, at the age of 66 years.

The application of telescopes and micrometers to graduated instruments forms an important epoch in the history of astronomy. This happy improvement was first brought into use by Picard in 1667. Morin, indeed, had applied a telescope to the quadrant so early as 1634, and perceived the stars in full day in 1635. In 1669 Picard began to observe the stars on the meridian in the daytime, with a quadrant, to which, in concert with Azout, he had applied an astronomical telescope having cross wires in its focus. Huygens invented the plate micrometer in 1650; Malvasia that with the fixed wires in 1662; and Azout that with the movable wire in 1666. (See Delambre, *Astronomie du Moyen Age*, p. 618. Note by Bouvard.) It is principally to the happy discoveries and ingenious inventions just referred to, and the fine application of the pendulum to clocks by Huygens in 1656, that we must attribute the rapid progress since made in practical astronomy, and the extreme precision of modern observations. Picard was also the first who introduced the modern method of determining the right ascensions of the stars, by observing their meridional passages, and employed the pendulum for that purpose. He likewise introduced the method of corresponding altitudes, and is entitled to be regarded as the founder of modern astronomy in France.

Roemer, the friend and pupil of Picard, discovered the progressive motion of light in 1675, and measured its velocity by means of the eclipses of Jupiter's satellites. He was the first who erected a transit instrument, which gave a new accuracy to observations of right ascension.

The Royal Observatory of Paris was completed in 1670, and its direction intrusted to Dominic Cassini. This celebrated astronomer was born at Perinaldo, in the county of Nice, and educated in a college of the Jesuits at Genoa. He acquired an early passion for astronomical observations; and in 1644 was invited to Bologna by the marquis Malvasia, where, in 1650, he succeeded Cavalleri

Dominic
Cassini,
born 1626,
died 1712.

History. as professor of astronomy. In this situation he continued till 1669, when he went to Paris on the invitation of Louis XIV. He was naturalized in France in 1673, and continued in the charge of the observatory till his death, which happened in 1712.

Cassini enriched astronomy with a great number of curious observations and discoveries. He determined the motions of Jupiter's satellites from observations of their eclipses, and constructed tables of them, which were found to be remarkably exact. He observed that the ring of Saturn is double, and discovered four of the satellites of that planet. He also determined the rotation of Jupiter and Mars, and made a number of observations on Venus with the same view. He observed the zodiacal light, and made a near approximation to the parallax of the sun. We also owe to him the first table of refractions, calculated on correct principles; and a complete theory of the libration of the moon. Galileo had only observed the libration in latitude; Hevelius explained the libration in longitude, by supposing that the moon always presents the same face to the centre of her orbit, of which the earth occupies a focus. Cassini made the important remark, that the axis of rotation of the moon is inclined to the ecliptic, and that its nodes coincide with those of the lunar orbit, so that the poles of the orbit, ecliptic, and equator of the moon, are on the same circle of latitude, the pole of the ecliptic being situated between the other two. The greater number of these discoveries are, however, only of secondary importance; and it must be confessed that Cassini took no part in the great and permanent improvements which astronomy received in that age. He has, nevertheless, obtained an extraordinary reputation. Lalande remarks, that in his hands astronomy underwent the most signal revolutions, and that his name is, in France, almost synonymous with that of creator of the science. Delambre has, however, taken a different and far more accurate view of the real services of Cassini. "The revolution in Astronomy," this judicious critic observes, "was brought about by Copernicus, by the laws of Kepler, by the pendulum of Huygens, the micrometers of Azout and Picard, by the sectors and mural of Picard, and his method of corresponding altitudes, by the transit instruments of Roemer; and Cassini appears to us an entire stranger to all these innovations. He followed another route; he devoted a long life to painful observations, which at last deprived him of sight. Let us not refuse him the praise which he has so well merited, but let us reserve a place in our esteem for labours less brilliant perhaps, but of greater and more permanent utility, and which evince at least equal talent and sagacity."

Maraldi. Cassini was assisted in his observations by his nephew, James Philip Maraldi, who determined the regression of the nodes, and the progressive motion of the apsides of the orbit of Jupiter. This astronomer also corrected the theory of Mars, and observed the sun's parallax. He rejected the hypothesis of the progressive motion of light, as being insufficient to explain the inequalities of Jupiter's satellites; and he conceived the design of forming a new catalogue of the stars, which, however, was never executed. He died in 1729.

Progress of science in the 17th century. There is no period in the history of mankind so distinguished by great and important discoveries, or so remarkable for the rapid development of the human intellect, as the seventeenth century. We have already noticed the invention of the pendulum, and its application to regulate the motion of time-keepers; of the telescope, and some of the phenomena of the new worlds it has exposed to view; of the logarithms, by which computations are so much abridged; and of the mechanical contrivances for measur-

History. ing minute angles in the heavens. The same century witnessed the application of algebra to geometry, the discovery of the laws of the planetary motions, of the infinitesimal calculus, the acceleration of falling bodies, the sublime theory of central forces, and the great principle of gravitation which connects the celestial orbs, and regulates the motions which it had been the business of the astronomer to observe since the earliest ages of the world. The different steps which conducted to this important discovery, and the immediate consequences deduced from it by its immortal author, are so fully developed in the admirable Dissertation on the Progress of the Physical Sciences, in this Encyclopædia, that it is unnecessary to enter into any detail respecting them here; we may only remark, that if observation has furnished the data for the discovery of the mechanical principle and primordial laws of the universe, the knowledge of these laws has been, in turn, of the most essential service to observation, by guiding and directing it to its most important objects. Many of the inequalities of the planetary motions, in consequence of their minuteness and the slowness with which they vary, could not have been detected by observation; others might perhaps have been perceived, but we should still have been ignorant whether their constant accumulation might not ultimately change the state of the system, and, by destroying all confidence in the tables, demolish the fabric which had been reared at such a vast expense of time and labour. But when these inequalities are detected by theory, and separated from the mean motions with which they were blended, it becomes an object of the highest interest to confirm their existence by the most delicate and accurate observations. Hence, a more refined practice has constantly followed every theoretical discovery. Besides, it is the perfection of theory, and not the mere knowledge of isolated facts, which gives astronomy its greatest value in the eyes of the philosopher. Numerous and important as its applications are, they have but a subordinate interest, in comparison of the knowledge of those general laws to which every particle of matter in the universe is subject, and by the discovery of which man has penetrated so deeply into the mysteries of nature.

By the discovery of the law of gravity Newton laid the foundations of physical astronomy; and by the consequences which he deduced from that law, proceeded far in the erection of the superstructure. He showed that the motions of all the bodies of the planetary system are regulated by its influence; he determined the figure of the earth on the supposition of its homogeneity; he gave a theory of the tides, discovered the cause of the precession of the equinoxes, and determined some of the principal lunar inequalities and planetary perturbations. Many of his theories were left in an imperfect state; for it is not in matters of science that it is given to the same individual to invent and bring to perfection: their complete development required that several subsidiary sciences should be farther advanced; but it has been the triumph of his system, that every subsequent discovery has only tended to strengthen and confirm it. This bright ornament of the human genius was born on the 25th of December 1642, the day of the death of Galileo, and died on the 20th of March 1727, in the 85th year of his age.

While physical astronomy was undergoing a complete revolution in the hands of Newton, the practical part was receiving great improvement from Flamsteed, the first astronomer royal, who conducted the Greenwich Observatory. This celebrated institution, from which so many important discoveries have emanated, was erected under the reign of Charles II. in 1675. Flamsteed was appoint-

History ed to it in 1676, and continued with indefatigable zeal to discharge the duties of the office during the long period of 33 years. In the course of this time he made an immense number of excellent observations, the results of which are given in the *Historia Cælestis*, the first edition of which was published in 1712, at the expense of Prince George of Denmark, the husband of Queen Anne. The second appeared in 1723, some time after the death of the author, in three volumes folio. The first volume contains the observations which he made, first at Derby, and afterwards at Greenwich, on the fixed stars, planets, comets, spots of the sun, and Jupiter's satellites. The second volume contains the transits of the planets and stars over the meridian, and the places of the planets deduced from these observations. The third contains an historical notice, in which he gives a description of the instruments used by Tycho and himself; catalogues of fixed stars by Ptolemy, Ulugh Beigh, Tycho, the landgrave of Hesse, and Hevelius; together with the British Catalogue, containing the places of 2884 stars. The labours of Flamsteed were, however, confined entirely to the practical part of astronomy. He made no improvements in theory; but he is entitled to the merit of having been the first who brought into common use the method of simultaneously observing the right ascension of the sun and a star, a method by means of which the determination of the positions of the stars is reduced to the observation of meridional transits and altitudes. He was likewise the first who explained the true principles of the equation of time; and he improved the lunar tables by introducing into them the annual equation which had been suggested by Horrox. The *Atlas Cælestis*, another posthumous work of Flamsteed, was published in 1753.

Halley, born 1656, died 1742. Flamsteed was succeeded in the observatory by Dr Halley, a philosopher whose inventive genius and indefatigable activity rendered him one of the brightest ornaments of his country. Halley was the son of a wealthy citizen of London, where he was born on the 8th of November 1656. From his earliest years he applied himself with ardour to the study of mathematics and astronomy; and having procured a few instruments, he began to make observations, by which he was led to remark the inaccuracy of the tables of Jupiter and Saturn. In his 19th year he published a direct and geometrical method of finding the eccentricities and aphelia of the orbits of the planets; and in the year following he undertook a voyage to St Helena, with a view to form a catalogue of the stars in the southern hemisphere. The station was unfortunately chosen, for, owing to the incessant rains and foggy atmosphere of that island, he was able to determine the places of only 360 stars in the course of a whole year. He had, however, the satisfaction of observing a transit of Mercury over the sun's disk, a phenomenon which suggested to him the important remark, that the transits of the inferior planets might be advantageously employed in determining one of the most essential elements of the planetary system, viz. the parallax of the sun, and consequently the diameters of the orbits. The method has since been successfully employed in the case of Venus: the transits of Mercury, though much more frequent, are not so well adapted to the purpose. On his return from St Helena he was commissioned by the Royal Society to visit Hevelius at Dantzic, and determine, by a direct comparison of observations, the dispute which had arisen between that astronomer and Dr Hooke respecting the relative advantages of plain and telescopic sights. After this Halley for some time travelled on the Continent, and on his return to England devoted himself entirely to scientific pursuits. The fruits of his leisure soon began to appear in the multitude of treatises

History which he published from time to time in every department of the mathematical and physical sciences. The most important of those connected with astronomy was his *Synopsis Astronomiæ Cometicæ*,—a work abounding in profound and original views, and which, in respect of theory, formed perhaps the most remarkable accession to the science that had been made since the time of Kepler. In this work he revived an ancient opinion, that the comets belong to the solar system, and move in very eccentric orbits round the sun, returning after stated but long intervals. He also ventured to predict that the comet of 1681 would again return to its perihelion in 1759,—the first prediction of the kind that was verified. In 1720 Dr Halley was appointed to succeed Flamsteed in the Royal Observatory; and though now in the 64th year of his age, he undertook, with a view to improve the lunar theory, to observe the moon through a whole revolution of her nodes, erroneously supposing, that after such a revolution the errors of the tables would again appear in the same order. He was the first who, by a comparison of ancient and modern observations, remarked the acceleration of the mean motion of the moon, and thus called the attention of mathematicians to an important and curious phenomenon, the physical cause of which was at length detected by the powerful analysis of Laplace. He was also the first who pointed out the secular inequalities of Jupiter and Saturn, occasioned by their mutual perturbations,—a theory that formed the subject of several profound memoirs of Euler and Lagrange, and for the complete development of which astronomy is likewise indebted to Laplace. Besides these important discoveries in astronomy, the labours of Dr Halley also greatly contributed to the promotion of geometry and navigation. He undertook two long voyages, and traversed the Pacific Ocean to observe the deviations of the magnetic needle; and posterity will gratefully recollect that it was through his pressing solicitations that Newton consented to the publication of the *Principia*. In 1703 he succeeded Dr Wallis as professor of geometry at Oxford. He became secretary of the Royal Society in 1713, and died at Greenwich in 1742.

The discoveries of Bradley, who succeeded Halley as astronomer royal, form a memorable epoch in the history of the science. This great astronomer was born at Sherborne in Gloucestershire in 1692, and acquired from his uncle, Mr Pound, an early taste for astronomical observation. He was destined for the church, and for some time held a curacy, which he resigned in 1721, on being appointed to succeed Keill as Savilian professor of astronomy at Oxford. His first essays indicated no extraordinary talent; but an opportunity having presented itself of engaging in more important researches, he embraced it with ardour; and by his sagacity and perseverance was conducted to two discoveries which have entirely changed the face of astronomy.

A singular motion of the polar star had been observed by Picard, of which, however, that astronomer could neither assign the law nor give any satisfactory explanation. He only remarked that the inequality was annual, and amounted to about 40 seconds. Hooke, in 1674, a few years after the observations of Picard, imagined that he had discovered a parallax in some of the stars; and Flamsteed, following the ideas of Hooke, explained, by means of parallax, the minute changes of position which he had observed in Polaris and some circumpolar stars. Manfredi and Cassini demonstrated the error of Flamsteed, but were not more successful in their attempts to explain the motion in question. Samuel Molyneux conceived the idea of verifying all that had been said respecting the

History. supposed parallaxes, and for this purpose commenced a series of observations at Kew, with an excellent 24 feet sector constructed by Graham. Bradley, who happened at that time to reside at Kew, took a part in these observations, the result of which was, that the remarks of Picard were confirmed beyond the possibility of doubt. It was, however, abundantly evident that the apparent motions alluded to were not connected in any manner with parallax; it therefore became an object of the greatest interest to determine their physical cause, and assign their law and period. The first idea that occurred was to inquire whether they arose from a change of position in the earth's axis; but this supposition was found to be inadequate to the explanation of the phenomena. Molyneux having been in the mean time appointed a lord of the admiralty, the observations were discontinued at Kew; they were, however, shortly after resumed by Bradley at Wanstead, with a smaller but more convenient instrument; and after they had been continued several years, it was found that the star (γ draconis) on which they were principally made, appeared to describe annually a small ellipse, the transverse axis of which amounted to 40". This was an important determination; for the ellipse afforded the means of computing at all times the aberration of any star whatever, whether in longitude, latitude, declination, or right ascension. Bradley also pointed out the physical cause of the aberration, and demonstrated that it resulted from the combination of the motion of light with the annual motion of the earth. This capital discovery was made in 1728.

Discovery of the nutation of the terrestrial axis. Bradley, anxious to verify his ingenious theory, continued his observations, and soon felt the difficulty that had so much embarrassed Picard. The places of the stars, calculated according to his formula for the aberration, could not be reconciled with the observations. The errors continued to augment during nine years, after which they went on diminishing during the nine years following. This inequality, of which the period, like that of the nodes of the moon, was 18 years, was readily explained by supposing a slight oscillation of the earth's axis, occasioned by the action of the moon on the protuberant parts surrounding the equator of the terrestrial spheroid. After assiduously observing its effects during twenty years, Bradley found that the phenomena could be accurately represented by giving the pole of the equator a retrograde motion about its mean place in an ellipse whose axes are 18" and 16", and completing its revolution in the period of 18 years. This result was communicated to the Royal Society in 1748. To these two grand discoveries of Bradley, the aberration and nutation, modern astronomy is wholly indebted for all its accuracy and precision; and, as Delambre remarks, they assure to their author a distinguished place, after Hipparchus and Kepler, above the astronomers of all ages and all countries.

Bradley was appointed astronomer royal in 1741, and from this time to the period of his death made an immense number of observations, which were presented by his heirs to the university of Oxford, on condition that they should forthwith be published. The first volume appeared only in 1798, edited by Dr Hornsby. The rest were committed to the care of the late Dr Abraham Robertson, and appeared in 1805. Dr Bradley was chosen a corresponding member of the Academy of Sciences in 1748. In 1752, twenty-four years after his great discovery of the aberration of light, he was admitted into the Royal Society. He died on the 13th of July 1762, in the 70th year of his age.

While England was deriving so much glory from the brilliant discoveries of Bradley, France produced a multi-

tude of excellent astronomers, by whose successful labours every department of the science was signally promoted. Among these Lacaille is pre-eminently distinguished, both by the variety and importance of his observations, and the indefatigable zeal with which, during twenty-two years, he prosecuted the most laborious researches. He commenced his astronomical career in 1739, by assisting Cassini de Thury (grandson of the first Cassini) in the verification of the measurement of the meridian through France. In 1751 he undertook a voyage to the Cape of Good Hope, the primary objects of which were to determine the sun's parallax, by means of observations on the parallaxes of Mars and Venus, while similar observations were made in Europe; and to form a catalogue of the southern circumpolar stars. No undertaking for the benefit of science was ever more successfully executed. In the course of a single year, Lacaille, without assistance, observed upwards of ten thousand stars, situated between the tropic of Capricorn and the pole, and computed the places of 1942 of them; a labour which would scarcely be credited, if the details of his observations had not been published in the *Cælum Australe Stelliferum*, a work which was given to the world in 1763. Our admiration of the rapid execution of this vast undertaking will be increased, when we consider, that during the same time he measured a degree of the meridian, and made numerous observations on the moon simultaneous with those of Lalande, who observed at Berlin, in order to determine the moon's parallax, by means of direct observations made at the extremities of a meridional arc of upwards of 85 degrees. Before his return to Europe, he visited the isles of France and Bourbon, where he measured the length of the pendulum, and made numerous remarks on the natural and civil history of those countries. Astronomy is likewise indebted to Lacaille for a table of refractions which he computed from a comparison of above 300 observations made at the Cape and at Paris. In 1757 he published his *Astronomiæ Fundamenta*, in which he gave rules and tables for computing the apparent motions of the stars, which continued to be employed till Lambert supplied the corrections depending on the nutation, and Delambre those depending on the aberration. To defray the expense attending the publication of this important work, which he distributed in presents to the different observatories and astronomers in Europe, he submitted to the drudgery of calculating ephemerides during ten years. Lacaille composed several elementary works for the use of the students in the college of Mazarin, where he occupied the chair of astronomy, and inserted a great number of memoirs in the volumes of the Academy of Sciences. This great astronomer, distinguished as much by the excellence of his moral qualities as his profound knowledge and indefatigable zeal, died suddenly in 1762.

The Royal Observatory of Paris continued under the direction of the family of Dominic Cassini during 120 years. James Cassini, the second of that name, is principally known by a work on the magnitude and figure of the earth, and his *Elements of Astronomy*. He seems not to have duly appreciated the new discoveries which were daily making around him. His *Elements*, published in 1740, contains no mention of the aberration; and he adopted the opinion that the earth is elongated instead of being flattened at the poles. His son, Cassini de Thury, was chiefly occupied with the meridian, and the geometrical survey of France. The last astronomer of the family, the Count de Cassini, was obliged to resign the observatory at the revolution.

The question of the figure of the earth furnished ample materials for the practical as well as the speculative measurement of the earth.

History. tronomer during the last century. The results of the measurement of the meridian by Cassini were at variance with the theories of Newton and Huygens; and the Academy of Sciences resolved on making a decisive experiment by the actual measurement of the lengths of two degrees, one at the equator, and another in as high a latitude as could be reached. In the year 1735, three astronomers, Godin, Bouguer, and La Condamine, were commissioned by the French government to accomplish the first of these objects in Peru; and the year following, Maupertuis, Clairaut, Camus, and Lemonnier, went to Lapland to execute the second under the polar circle. Notwithstanding the greater difficulties they had to contend with, the first party were the most successful; but the result of both operations established the compression of the earth at the poles. Bouguer published the details of the Peruvian measurement in an admirable work on the *Figure of the Earth*, in which he has also inserted an account of a great number of experiments made by him in the same country to determine the length of the seconds' pendulum, and the effects of the attraction of mountains on the plumb-line. Bouguer is likewise the author of an excellent treatise on light. This accomplished mathematician and experimenter did not adopt the Newtonian theory of gravitation, but he was the last apostle of the Cartesian philosophy in the Academy of Sciences.

It would greatly exceed the limits of this article to give even an abridged account of the numerous observers who, about this period, contributed to the improvement of every department of practical astronomy. We must therefore content ourselves with merely noticing the names of some of the most distinguished, leaving the details of their labours to be given in the biographical articles interspersed throughout the work.

Delisle,
born 1688,
died 1768.

Lemonnier,
died 1799.

Wargentin,
born 1717, died
1783.

Lalande,
born 1732,
died 1807.

Delisle formed a school of astronomy in Russia, and has left a method of computing the heliocentric places of the sun's spots, and of Mercury and Venus in their transits over the sun's disk, and likewise of determining, by means of the stereographic projection, the directions of their path when they enter and leave the disk. Lemonnier introduced the discoveries of Bradley into his *Astronomical Institutions*, and was the instructor of Lacaille and Lalande. He published a *Histoire Céleste*, containing a collection of observations from 1666 to 1685, and a number of other works and memoirs connected with astronomy. He made an immense number of observations, but their accuracy is far inferior to those of Bradley. Wargentin, secretary of the Academy of Sciences of Stockholm, devoted the whole of his life to the correction of the tables of the satellites of Jupiter. The theory of the satellites was not then far advanced; but when theory failed him, he profited by the remarks of others and by his own reflections, and endeavoured by repeated trials to find empirical equations capable of conciliating the tables with the best observations. By confining himself almost exclusively to this subject, he acquired a high reputation, and was ranked among the first astronomers of an epoch which abounds in great names. His tables of the satellites have, on account of their superior accuracy, been employed in determining the masses, and other elements, which serve as the basis of the analytical theories.

One of the most celebrated astronomers of the last century was Lalande. He commenced his early career by a set of lunar observations at Berlin, undertaken simultaneously with those of Lacaille at the Cape, for the purpose of determining the moon's horizontal parallax. On his return to Paris he was received, though only twenty-one years of age, into the Academy of Sciences; and on the

resignation of Delisle was appointed professor of astronomy in the college of France. By his extraordinary zeal, indefatigable activity, and the care which he took to have his name constantly before the public, Lalande soon became one of the most distinguished men of his day; but his reputation, acquired in a great measure from attention to subjects which had only an ephemeral interest, and not through any permanent or fundamental additions to science, has already begun to wane; and his works, many of which are of considerable utility, seem to have fallen into unmerited neglect. His character as an astronomer is fairly and impartially summed up by Delambre in the following terms:—"If Lalande did not renew the foundations of astronomical science, like Copernicus and Kepler,—if he did not, like Bradley, immortalize himself by two brilliant discoveries,—if he was not so learned and accurate a theorist as Mayer,—if he was not to the same degree as Lacaille an exact, expert, scrupulous, industrious, and indefatigable observer and calculator,—if he had not the constancy to attach himself, like Wargentin, to a single object, in order to become the first in a particular department,—and if, in all these respects, he was only an astronomer of the second rank,—he was the first of all as a professor. No one ever did more to propagate the knowledge and love of astronomy. It was his object to be useful and celebrated; and he succeeded, through his labours, his activity, his credit, and his solicitations: by means of a most extensive correspondence he incessantly laboured for the benefit of science: he even endeavoured to serve it after his death, by founding a medal, which the Academy of Sciences adjudges annually to the astronomer who has made the most interesting observation, or written the most useful memoir." (Delambre, *Astronomie du Moyen Age*.)

Bradley was succeeded in the Greenwich Observatory by Dr Bliss, who died in the course of a few years after his appointment. Dr Bliss was in turn succeeded by Dr Maskelyne, the late astronomer royal, under whose care the observatory maintained the high character which it acquired from the immortal labours of his illustrious predecessors. Dr Maskelyne began his astronomical career in 1761, when he was appointed to observe the transit of Venus at the island of St Helena, and endeavour to verify the existence of a small parallax of the star Sirius, which seemed to be indicated by the observations of Lacaille at the Cape. Unfortunately the state of the weather prevented him from observing the transit; and his observations on Sirius were abandoned in consequence of the discovery of a defect in the zenith sector which he had carried out with him for the purpose of making the observations in question. The main objects of his voyage were thus frustrated; but some indirect advantages resulted from it, which compensated in some measure for the disappointment. The attention of Ramsden was called to the sector, and a better method of constructing these instruments was devised. At St Helena he made several interesting observations on the tides, the variation of the compass, the moon's horary parallaxes, &c. In going out and returning home, he paid particular attention to the different methods of finding the longitude at sea, and practised that which depends on observations of the lunar distances from known stars, taken with a Hadley's sextant, or other reflecting instrument. He also composed a set of rules for the use of the seamen, which he published on his return, first in the *Philosophical Transactions*, and afterwards in the *British Mariner's Guide*. In the year 1765 he was appointed astronomer royal, and soon after recommended to the Board of Longitude the general adoption in the navy of the lunar method of finding the

History

Maskelyne, born 1732, died 1811.

History. longitude, and proposed that tables for facilitating that method should be calculated and published in the *Nautical Almanac*. This recommendation was adopted, and the Nautical Almanac continued to be published under his superintendence during forty-eight successive years. He also published a set of tables requisite to be used with that long-celebrated ephemeris; and by these means contributed to bring nautical astronomy to its present state of precision. Dr Maskelyne was most assiduous in the discharge of his important duties as astronomer royal. On one occasion only did he consent to leave the observatory, viz. when at the request of the Royal Society he proceeded to Scotland for the purpose of determining, by experiments on Schehallien, the deflection of the plumb-line occasioned by the attraction of the mountain. The result of the observations made on this occasion furnished data for the determination of the mean density of the earth, which Dr Hutton, by a laborious process of calculation, found to be about five times greater than that of water. Dr Maskelyne had the credit to procure, at the expense of the Royal Society, the regular publication of his observations, by which he rendered a great service to all the astronomers of Europe. The lunar method of determining the longitude, the Nautical Almanac, the catalogue of 36 stars, and some improvements in the construction of instruments, are the principal benefits for which astronomy is indebted to Dr Maskelyne.

Herschel, born 1738, died 1822. Sir William Herschel, born in Hanover in 1738, has rendered his name immortal by the discovery of a new planet without the orbit of Saturn, and thereby doubling the ancient boundaries of the solar system. Having settled in England, at Bath, he began to devote his leisure to the construction of telescopes and the polishing of reflecting mirrors. Endowed with equal skill and patience, he soon obtained instruments superior to any that had been known before, by means of which he was led to the most brilliant discoveries that have been made in the heavens since the time of Galileo. Being employed in making a review of the sky with a powerful telescope, he perceived, on the 13th of March 1781, near the feet of Gemini, a star of the fifth magnitude, having a disk perfectly well defined, and differing in appearance from the other stars which afforded the same quantity of light. On observing it with a telescope whose magnifying power was 932, he perceived its diameter was enlarged, while that of the stars underwent no change. These circumstances were sufficient to draw his attention to the star, and nothing more was requisite to enable him speedily to discover that it had a slow motion. He at first supposed it was a comet, and acquainted Dr Maskelyne with the discovery. The circumstance was soon made known at Paris; and it was gradually perceived, that as the distance of the star did not sensibly vary, it was necessary to regard it as a seventh planet. Herschel, in honour of his royal patron, gave it the name of the *Georgium Sidus*; but the mythological appellation of Uranus has prevailed. On the 11th of January 1787 he discovered two satellites revolving round the new planet, and subsequently found that it was accompanied by four others. It was soon noticed that Uranus had been observed by Flamsteed, Mayer, and Lemonnier, who had each supposed it to be one of the fixed stars. Their observations enabled Delambre to correct the elements of the orbit, and calculate tables of its motion. By means of his powerful telescopes Herschel determined the figure and rotation of Saturn, discovered the parallel belts on his surface, and perceived that the ring was double. In 1789 he discovered two new satellites belonging to this planet, and revolving within the ring. From some appearances indicated by the fixed stars,

Herschel was led to conclude that the whole solar system is in motion about some distant centre, and that its direction is at present towards the constellation Hercules,—a conclusion, however, which succeeding observations have not verified. His observations on nebulae and double stars have opened up a new field of research, boundless in extent, and interesting by reason of the variety of the objects it presents to the attention of the observer. The extraordinary activity with which he pursued his favourite occupations is attested by 67 memoirs communicated from time to time to the Royal Society. A great part of these, however, is filled with speculations of no value to astronomy; and his taste was rather to observe astronomical phenomena than to engage in computations, or the more arduous and essential, though less fascinating, labours through which the science can be really benefited. In the course of the following chapters we shall have frequent occasion to allude to his discoveries, and his ingenious speculations concerning the constitution of the sun and the sidereal heavens.

Few individuals have contributed so eminently to the perfection of modern astronomy as Delambre, the perpetual secretary of the Academy of Sciences. The scientific life of this illustrious astronomer did not commence till he had attained his 40th year; but from that time till his death it was occupied by a series of unremitting labours to enlarge the boundaries, and ameliorate the practice and theory of the science. Associated with Mechain, he was employed during the troubles of the revolution in measuring the meridian from Dunkirk to Barcelona,—a labour which was prosecuted with admirable zeal in the face of innumerable difficulties, and even dangers of the most formidable kind. By an immense number of excellent observations he determined the constants which enter into the formulæ deduced from theory by the profound researches of Lagrange and Laplace, and also formed a set of tables much more exact than any that had appeared before them. His *Astronomie Théorique et Pratique*, in three quarto volumes, contains the best rules and methods which have yet been devised for the guidance of the practical astronomer; and his *Histoire*, in six large volumes 4to, gives an account of every successive improvement which has been made in the science, and a full abstract of every work of celebrity which has been written respecting it, since the first rude observations of the Greeks to the end of the last century. It is invaluable to the historian, and will ever remain a proud monument of the profound learning and laborious research of its author.

The observatory which was established at Palermo, about the year 1790, under the active superintendence of Piazzi, holds a distinguished rank among the similar institutions of Europe. Piazzi, born in 1746, took the habit of the religious order of the *Theatins* at Milan, and finished his noviciate in the convent of St Anthony. Among his preceptors he had the advantage of counting Tiraboschi, Beccaria, Le Sœur, and Jacquier; and from these illustrious masters he speedily acquired a taste for mathematics and astronomy. After filling several professors' chairs in the colleges of the Jesuits at Rome and Ravenna, he was appointed in 1780 professor of the higher mathematics in the academy of Palermo. Here his first care was to reform the general system of education; and, by the alterations which he introduced, he contributed powerfully to dissipate the shades of ignorance, which, under the double influence of the Jesuits and the Inquisition, still lowered over the soil of Sicily. After having rendered this service to literature, he obtained from the prince of Caramanico, viceroy of the island, permission to found an observatory, and undertook a voyage to France and

History. England, in order to provide the instruments necessary for the new establishment. Having procured a vertical circle, a transit, and some other instruments from Ramsden, he returned to Palermo and commenced his observations. His first care was to prepare a new catalogue of stars, the exact positions of which he justly considered as the basis of all true astronomy. In prosecuting this object he did not content himself with a single observation, but before he fixed the position of any star, observed it several times successively; and, by this laborious but accurate method, he constructed his first great catalogue of 6748 stars, which was crowned by the Academy of Sciences of France, and received with admiration by the astronomers of all countries. His constant practice of repeating his observations led to another brilliant result, the discovery of an eighth planet. On the 1st of January 1801, Piazzi, searching for the star 87 of the catalogue of Mayer, cursorily observed a small star of the eighth magnitude, between Aries and Taurus. On the following day he remarked that the star had changed its position, and accordingly supposed it to be a comet. He communicated his observations to Oriani, who, seeing that this luminous point had no nebulosity like the comets, and that it had been stationary and retrograded within comparatively small limits like the planets, computed its elements on the hypothesis of a circular orbit. He found that this hypothesis agreed with the observations, and other astronomers soon confirmed its accuracy. He gave the planet the name of *Ceres Ferdinandea*, in honour of Ferdinand, king of Naples, in whose dominions it was discovered, and who proposed to consecrate the event by a gold medal, struck with the effigy of the astronomer; but Piazzi, nobly preferring the interests of science to vain honours which could add nothing to his glory, requested that the money destined for this purpose should be employed in the purchase of an equatorial, which was still wanting to his observatory. In 1814 he published a new catalogue, extended to 7646 stars,—a splendid monument of indefatigable zeal and activity. He made an uninterrupted series of solstitial observations from 1791 to 1816, for the purpose of determining the obliquity of the ecliptic, which, compared with those of Bradley, Mayer, and Lacaille, in 1750, give a diminution of 44" in a year. Besides these labours, sufficient to occupy a life of ordinary industry, Piazzi composed a number of memoirs for the different societies of which he was a member, and was intrusted by the Neapolitan government with several important commissions respecting the public instruction and the regulation of weights and measures in Sicily. He died in 1826, after having bequeathed his library and all his instruments to the observatory at Palermo, and assigned a liberal annuity to be devoted to the instruction of young men who evince a decided taste for astronomy.

Discovery of Pallas, Juno, and Vesta. The discovery of Ceres led to that of three other little planets, circulating at nearly the same distance from the sun,—a circumstance unique in the construction of the solar system. On account of the smallness of the new planet, and the nebulosity by which it is surrounded, the difficulty of finding it after it had for some time ceased to be observed, was so considerable, that Dr Olbers of Bremen was induced to examine, with particular care, the configurations of all the small stars situated in the vicinity of its path, in order to have the means of detecting it at any time with greater facility. While engaged in making observations for this purpose, he discovered, on the 28th of March 1802, and nearly in the same place where he had before observed Ceres, another planet similar in size and appearance, to which he gave the name of *Pallas*. The extraordinary circumstance of the discovery

of two planets having nearly the same mean distance, and performing their revolutions nearly in the same time, led Dr Olbers to imagine that Ceres and Pallas were fragments of a larger planet which had revolved in the same place, and been shattered by some external force or internal convulsion. The immediate consequence of this hypothesis was the probability of the existence of other fragments of the original planet, hitherto undiscovered; and that if such fragments existed, the planes of their orbits would pass through the points in which the orbits of Ceres and Pallas intersect each other. This bold idea acquired some probability from the subsequent discovery of two other planets in the very quarter of the heavens to which Dr Olbers had directed the attention of astronomers. *Juno* was discovered by M. Harding of Lilienthal, on the 2d of September 1804; and *Vesta*, by Dr Olbers himself, on the 29th of March 1807. Diligent observation has not since added to their number.

Astronomy is a science which borrows the aid of several other sciences, with which its advancement is simultaneous. Instruments capable of appreciating or measuring the exceedingly minute quantities about which the observer now concerns himself, could only be produced in a very advanced state of mechanics. In the accurate graduation of large instruments, our English artists have long maintained an unrivalled superiority. Graham, a celebrated watch-maker, united to great dexterity in the mechanical arts a decided taste for observation; and the extraordinary improvements which he effected in the art of dividing form an era in the history of practical astronomy. The sector used by Bradley, in the observations which led to the discovery of the nutation, was of his construction, and he was also the inventor of the first compensation pendulum. Sisson, who succeeded him, maintained in this department the honour and pre-eminence of England. Bird was originally a weaver in Durham, and first gave proof of his mechanical genius by dividing dials for the watch-makers in a manner far superior to what had been commonly practised. He was employed by Sisson in the division of mathematical instruments, and recommended by that artist to Graham, who instructed him in his methods. He constructed the 8 feet quadrants employed in the Greenwich and Paris observatories, and another of 6 feet for Mayer at the observatory of Göttingen. Ramsden invented a machine for the more accurate division of instruments, on account of which he received a premium from the Board of Longitude. The mural quadrants of this artist were held in high estimation, and the transit instrument, sextant, and refracting micrometer, in passing through his hands, received considerable ameliorations. His astronomical instruments in general were considered the best that could be procured in Europe. Mr Troughton, who at present stands the foremost of our British opticians, has more than rivalled his predecessors. In the hands of this distinguished artist and astronomer, the division of instruments has been carried to a degree of precision and accuracy which probably will never be surpassed; while the great improvements he has introduced into the methods of constructing and mounting large instruments, and his ingenious inventions to elude natural obstacles, and guard against the accidental derangements from which it is impossible altogether to protect them, entitle him to the high place which he holds by universal consent among the most eminent philosophers and original mechanicians of the age. The numerous circles and other instruments of his manufacture, whether in the hands of private individuals or deposited in the different public observatories, are considered as the finest specimens of

History. what art has yet accomplished for the advancement of astronomical science.

Progress of Physical Astronomy.

Having now endeavoured to give an account of the labours of those astronomers who have principally contributed to make us acquainted with the state of the heavens, and the order and succession of the various phenomena they exhibit, we will conclude this part of the article by briefly advertng to the profound researches of some illustrious mathematicians who have developed the theory of Newton, and raised the fabric of physical astronomy to its present proud elevation.

Problem of the three bodies

Although the law of gravitation, as proposed by Newton, had from the first been admitted by all the most eminent astronomers of Britain, it was for a long time either opposed or neglected on the Continent. In fact, great improvements were required both in analysis and mechanics before it admitted of other applications than had been made by its great author, or could be regarded as any thing more than a plausible hypothesis. Newton demonstrated, that if two bodies only were projected in space, mutually attracting each other with forces proportional directly to their masses, and inversely to the squares of their distance, they would each accurately describe an ellipse round the common centre of gravity; and the spaces described by the straight line joining that centre and the moving body, would be proportional to the time of description, according to the second law of Kepler. But when it is attempted to apply Newton's law to the case of the solar system, great difficulties immediately present themselves. Any one planet in the system is not only attracted by the sun, but also, though in a greatly smaller degree, by all the other planets, in consequence of which it is compelled to deviate from the elliptic path which it would pursue in virtue of the sun's attraction alone. Now, the calculation of the effects of this disturbing force was the problem which geometers had to resolve. In its most general form it greatly transcends the power of analysis; but there are particular cases of it, and those too the cases presented by nature, in which, by reason of certain limitations in the conditions, it is possible to obtain an approximate solution to any required degree of exactness. For example, the Sun, Moon, and Earth form in a manner a system by themselves, which is very slightly affected by the aggregate attractions of the other planets. In the same way the Sun, Jupiter, and Saturn form another system, in which the motions are very little influenced by the action of any other body. In these two cases, then, the number of bodies to be taken into consideration is only three; and in this restricted form, the problem, celebrated in the history of analysis under the denomination of the *Problem of the Three Bodies*, is susceptible of being treated mathematically. With the hope of ameliorating the lunar tables, and of completing the investigations which Newton had commenced in the *Principia*, three distinguished geometers, Clairaut, D'Alembert, and Euler, about the middle of the last century, undertook, simultaneously, and without the knowledge of each other, the investigation of the problem of the three bodies, and commenced that series of brilliant discoveries which it is the glory of our own times to have seen completed.

Clairaut's solution of the problem of the three bodies was presented to the Academy of Sciences in 1747, and was applied to the case of the moon. From this solution he deduced with great facility, not only the inequality of the variation, which Newton had obtained by a more complicated, though at the same time a very ingenious me-

thod, but also the evection, the annual equation, and many other inequalities which Newton had not succeeded in connecting with his theory. It happened, however, curiously enough, that in the calculation of one effect of the disturbing force, namely, the progression of the moon's apogee, Clairaut was led into an error which produced a result that threatened to overturn the system of gravitation. The error consisted in the omission of some of the terms of the series expressing the quantity in question, which he wrongly supposed to have only an insensible value; and by reason of this omission, his first approximation gave only half of the observed progressive motion of the apogee. As this result was confirmed by D'Alembert and Euler, who had both fallen into the same error, it seemed to follow, as a necessary consequence, either that the phenomenon depended on some other cause than the disturbing force of the sun, or that the law of gravity was not exactly proportional to the inverse square of the distance. The triumph which this result gave to the Cartesians was not of long duration. Clairaut soon perceived the cause of his error; and by repeating the process, and carrying the approximations farther, he found the computed to agree exactly with the observed progression,—a result which had the effect of dissipating for ever all doubt respecting the law of gravity. The researches of Clairaut were followed by a set of lunar tables, much more correct than any which had been previously computed.

The return of the comet of 1682, which Halley had predicted for the end of 1758, or beginning of 1759, afforded an excellent opportunity for putting to the test both the theory of gravity and the power of the new calculus. Clairaut applied his solution of the problem of the three bodies to the perturbations which this comet sustained from Jupiter and Saturn, and, after calculations of enormous labour, announced to the Academy of Sciences, in November 1758, that the comet would return in the beginning of the following year, and pass through its perihelion about the 15th of April. It returned according to the prediction, but passed its perihelion on the 13th of March. The correction of an error of computation reduced the difference to nineteen days; and if Clairaut had been aware of the existence of the planet Uranus, he might have come still nearer the truth.

Besides these important researches on the system of the world, Clairaut composed an admirable little treatise on the figure of the earth, in which he gave the differential equations, till then unknown, of the equilibrium of fluids, whether homogeneous or heterogeneous, supposing an attractive force, following any law whatever, to exist among the molecules. He applied these equations to the earth; demonstrated that the elliptic figure satisfies the conditions of equilibrium; assigned the ellipticity of the different strata of which the earth may be supposed to be formed, together with the law of gravitation at the exterior surface. He likewise discovered the important theorem which establishes a relation between the oblateness of the terrestrial spheroid and the increase of gravitation towards the poles, on every supposition which can be imagined relative to the interior construction of the earth. By means of this theorem the ellipticity of the spheroid is deduced from observations of the lengths of the seconds' pendulum at different points of the earth's surface.

D'Alembert, as has already been mentioned, presented D'Alembert's solution of the problem of the three bodies to the Academy of Sciences at the same time with Clairaut. In the year 1749 he published his treatise on the precession of the equinoxes,—a work remarkable in the history of analysis and mechanics. By means of his newly invented

History.

Clairaut, born 1713, died 1765.

1783.

History. calculus of *Partial Differences*, and the discovery of a fertile principle in dynamics, he determined from theory the rate of the precession, which is nearly $50''$ in a year. He also determined the nutation of the earth's axis, which had been discovered by Bradley, and assigned the ratio of the axes of the small ellipse which the true pole of the earth describes around its mean place, in the same time in which the nodes of the lunar orbit complete a revolution. The solution of this problem led to the determination of the ratio of the attractive forces of the sun and moon, which D'Alembert found to be that of seven to three very nearly; whence he inferred that the mass of the earth is 70 times greater than that of the moon. He proved likewise that the precession and nutation are the same in every hypothesis concerning the interior constitution of the earth. In 1754 he published the first two volumes of his *Researches on the System of the World*. In this work he applied the formulæ by which he had calculated the motions of the moon to the motions of the planets disturbed by their mutual attraction, and pointed out the simplest method of determining the perturbations of the motions of a planet occasioned by the action of its own satellites. D'Alembert also treated the subject of the figure of the earth in a much more general manner than had been done by Clairaut, who had confined his investigations to the case of a spheroid of revolution. He determined the attraction of a spheroid of small eccentricity, whose surface can be represented by an algebraic equation of any order whatever, and even supposing the spheroid to be composed of strata of different densities.

The works of D'Alembert, which are extremely numerous, abound generally in profound and original views, and contributed greatly to the advancement of the physical and mathematical sciences; but it is to be regretted that they are very frequently deficient in that perspicuity and order so necessary in abstruse speculations, and that the course of his reasoning can be followed with difficulty when he descends into the detail of analytical operations. He had a horror of calculation, and delighted in general considerations and speculations which frequently turned on matters of pure curiosity.

Euler, born 1707, died 1783. The first memoir of Euler on the planetary perturbations was transmitted to the secretary of the Academy of Sciences in July 1747, some months before Clairaut and D'Alembert had communicated their solutions of the problem of the three bodies, and it carried off the prize which the academy had proposed for the analytical theory of the motions of Jupiter and Saturn. In this memoir Euler gave the differential equations of the elements of the disturbed planet, but suppressed the analysis by which he had been conducted to them. This analysis, however, he subsequently expanded in two memoirs, the first of which appeared in the Berlin Memoirs in 1749, and the second in those of Petersburg in 1750. Of these supplementary memoirs the first is remarkable on several accounts. It contains the first example of a method which has been fruitful of important consequences—namely, that of the variation of the arbitrary constants in differential equations, and the development of the radical quantity which expresses the distance between two planets in a series of angles, multiples of the elongations. The expressions which he gave for the several terms of this series were simple and elegant; and he demonstrated a curious relation subsisting among any three consecutive terms, by means of which all the terms of the series may be calculated from the first two. He was thus enabled to develop the perturbing forces in terms of the sines and cosines of angles increasing with the time, and thereby to surmount a very great analytical difficulty. Not-

History. withstanding, however, the great merit of Euler's memoir, several of the formulæ expressing the secular and periodic inequalities were found to be inaccurate; and in order to procure a correction of these errors, and give greater perfection to so important a theory, the academy again proposed the same subject for the prize of 1752. This prize was also carried off by Euler. In the memoir which he presented on this occasion, he considered simultaneously the motions of Jupiter and Saturn, and determined, in the first instance, the amount of their various inequalities, independently of the consideration of the eccentricities of their orbits. Pushing the approximations farther, and having regard to the inequalities depending on the eccentricities, he arrived at a most important result relative to the periodic nature of the inequalities occasioned by the mutual perturbations of the planets; which laid the foundation of the subsequent discovery by Lagrange and Laplace of the permanent stability of the planetary system. He demonstrated that the eccentricities and places of the aphelia of Jupiter and Saturn are subject to constant variation, confined, however, within certain fixed limits, which it never exceeds; and he computed that the elements of the orbits of the two planets recover their original values after a lapse of about 30,000 years. In the year 1756 the Academy of Sciences crowned a third memoir of Euler on the same subject as the two former, namely, the inequalities of the motions of the planets produced by their reciprocal attractions. This memoir, analytically considered, is also of great value. The method which he followed and illustrated has since been generally adopted in researches of the same nature, and consists in regarding as variable, in consequence of the disturbing forces, the six elements of the elliptic motion, viz. 1st, the greater axis of the orbit, which, by the law of Kepler, gives the ratio of the differential of the mean longitude to the element of the time; 2d, the epoch of this longitude; 3d, the eccentricity of the orbit; 4th, the motion of the aphelion; 5th, the inclination of the orbit to a given fixed plane; and, 6th, the longitude of the node. By considering separately the variations introduced into each of these elements by the disturbing forces, Euler obtained some important results; but even in this memoir his theory was not rendered complete. He did not consider the variation of the epoch; and the expression which he gave for the motion of the aphelion did not include that part of it which depends on the ratio of the eccentricities of the orbits of the disturbed and disturbing planet. Besides, the present memoir, like the two former, contained several errors of computation, which, by leading to results known to be wrong, probably prevented the author himself from being aware of the full value of the ingenious methods of procedure which he had exposed. Euler concluded this important memoir by making an extended application of his formulæ to the orbit of the earth as disturbed by the action of the planets. From some probable suppositions, first employed by Newton, relative to the ratios of the masses of the planets to that of the sun, he determined the variation of the obliquity of the ecliptic at $48''$ in a century,—a result which agrees well with observation. By this determination the secular variation of the obliquity of the ecliptic, which had been regarded by Lahire, Lemonnier, D'Alembert, and other eminent astronomers, as uncertain, was placed beyond doubt. The three memoirs which we have mentioned contain the principal part of Euler's labours on the perturbations; but physical astronomy is indebted to him for many other researches. He gave a solution of the problem of the precession of the equinoxes, and made several important steps in the lunar theory, with which he seems to have

History. occupied himself before he undertook the investigation of the planetary perturbations. In the year 1772, when entirely blind, he directed his son, Albert Euler, and two illustrious pupils, Kraft and Lexell, in the composition of a work of enormous labour on the same subject, which was undertaken with a view to discover the cause of the moon's acceleration. This work was concluded with a set of lunar tables deduced entirely from theory; but they were found to be far inferior to those of Mayer, and in some respects hardly equal to those of Clairaut.

The labours of Euler form an epoch in the history of the mathematical sciences. From the arithmetic of sines, and the simplest formulæ of trigonometry up to the variation of the arbitrary constants of differential equations, there is hardly an analytical theory which has not received extension or improvement from the creative powers of his great mind. The transactions of the Berlin and Petersburg Academies are filled with his inestimable productions; and if fecundity were not itself one of the attributes of genius, the number of the profound and laborious researches in which he was engaged would appear altogether incredible.

May's lunata- bles. The first theory of Euler formed the basis of the excellent lunar tables which were calculated by Tobias Mayer, and first published in the Memoirs of the Academy of Göttingen in 1753. Mayer was a skilful astronomer, and determined the co-efficients of the arguments of the different lunar inequalities from his own observations. He continued to correct and improve his tables till the time of his death, which happened in 1762, when a copy of them, containing his last corrections, was presented by his widow to the Board of Longitude in London. Bradley ascertained their accuracy by comparing them with a great number of his own observations, and made so favourable a report concerning them, that the Board of Longitude presented the widow of Mayer with a gratuity of L.3000. They were printed along with the author's lunar theory in 1765. Subsequently, the Board of Longitude directed Mason, who had been assistant to Bradley, to revise them, under the superintendence of Dr Maskelyne. Mason compared them with about 1200 of Bradley's observations; he corrected the co-efficients of Mayer, and introduced some new equations which had been indicated by that astronomer, but which he had considered as too uncertain, or of too small a value, to render it necessary to load his tables with them. Mayer's tables, thus corrected, were published in 1784, and for a long time continued to be the most accurate that had appeared.

The solution of the problem of the three bodies by Clairaut, D'Alembert, and Euler, gave rise to many other important works relative to the theory of the moon, into the merits of which, however, our limits will not permit us to enter. Thomas Simpson, Walmesley, Frisi, Lambert, Schulze, and Matthew Stewart, treated the subject with more or less success; but the complete explication of the theory of the lunar and planetary perturbations was reserved for two mathematicians, whose discoveries perfected the theory of gravitation, and explained for the last inequalities which remained to be accounted for in the celestial motions,—we mean Lagrange and Laplace.

In the year 1764, the Academy of Sciences of Paris, which had so successfully promoted the great efforts that had already been made to perfect the theory of attraction, proposed for the subject of a prize the theory of the libration of the moon. This was considered as an appeal to the genius of Lagrange, whose splendid talents had suddenly shone forth in two profound papers on the theory of sound, inserted among the Memoirs of the Turin Academy, and in which the calculus of variations was first

explained and made use of. Lagrange had the honour of carrying off the prize; but although he treated the subject in a manner altogether new, and with extraordinary analytical skill, he did not on this occasion arrive at a complete solution of the problem. In 1766 he obtained another prize for a theory of Jupiter's satellites. In the admirable memoir which Lagrange presented to the academy on this subject, he included in the differential equations of the disturbed motion of a satellite, the attracting force of the sun, as well as of all the other satellites, and thus, in fact, had to consider a problem of six bodies. His analysis of this problem is remarkable, inasmuch as it contained the first general method which was given for determining the variations which the mutual attractions of the satellites produce in the forms and positions of their orbits, and pointed out the route which has since been so successfully followed in the treatment of similar questions.

Of all the grand discoveries by which the name of Lagrange has been immortalized, the most remarkable is that of the invariability of the mean distances of the planets from the sun. We have already mentioned that Euler had perceived that the inequalities of Jupiter and Saturn, in consequence of their mutual actions, are ultimately compensated, though after a very long period. In prosecuting this subject, which Euler had left imperfect, Laplace had discovered that, on neglecting the fourth powers in the expressions of the eccentricities and inclinations of the orbits, and the squares of the disturbing masses, the mean motions of the planets, and their mean distances from the sun, are invariable. In a short memoir of 14 pages, which appeared among those of the Berlin Academy for 1776, Lagrange demonstrated generally, and by a very simple and luminous analysis, that whatever powers of the eccentricities and inclinations are included in the calculation of the perturbations, no secular inequality, or term proportional to the time, can possibly enter into the expression of the greater axis of the orbit, or, consequently, into the mean motion connected with it by the third law of Kepler. From this conclusion, which is a necessary consequence of the peculiar conditions of the planetary system, it results that all the changes to which the orbits of the planets are subject in consequence of their reciprocal gravitation, are periodic, and that the system contains within itself no principle of destruction, but is calculated to endure for ever.

In 1780 Lagrange undertook a second time the subject of the moon's libration; and it is to the memoir which he now presented to the Berlin Academy that we must look for the complete and rigorous solution of this difficult problem, which had not been resolved before in a satisfactory manner, either on the footing of analysis or observation. In the same year he obtained the prize of the Academy of Sciences on the subject of the perturbations of comets. In 1781 he published, in the Berlin Memoirs, the first of a series of five papers on the secular and periodic inequalities of the planets, which together formed by far the most important work that had yet appeared on Physical Astronomy since the publication of the *Principia*. This series did not, properly speaking, contain any new discovery; but it embodied and brought into one view all the results and peculiar analytical methods which had appeared in his former memoirs, and contained the germs of all the happy ideas which he afterwards developed in the *Mécanique Analytique*.

On account of the brilliant discoveries and important labours which we have thus briefly noticed, Lagrange must be considered as one of the most successful of those illustrious individuals who have undertaken to perfect the theory of Newton, and pursue the principle of gravi-

History. Discovery of the invariability of the mean distances.

Lagrange, born '36, died '13.

History. tion to its remotest consequences. But the value of his services to science are not limited to his discoveries in physical astronomy, great and numerous as they were. After Euler, he has contributed more than any other individual to increase the power and extend the applications of the calculus, and thereby to arm future inquirers with an instrument of greater power, by means of which they may push their conquests into new and unexplored fields of discovery.

Laplace,
born 1749,
died 1827.

With the name of Lagrange is associated that of Laplace, whose rival labours divided the admiration of the scientific world during half a century. Like Newton and Lagrange, Laplace raised himself at an early age to the very highest rank in science. Before completing his 24th year, he had signalized himself by the capital discovery of the invariability of the mean distances of the planets from the sun, on an hypothesis restricted, indeed, but which, as we have already mentioned, was afterwards generalized by Lagrange. About the same time he was admitted into the Academy of Sciences, and thenceforward devoted himself to the development of the laws which regulate the system of the world, and to the composition of a series of memoirs on the most important subjects connected with astronomy and analysis. His researches embraced the whole theory of gravitation; and he had the high honour of perfecting what had been left incomplete by his predecessors.

Discovers
the cause
of the
moon's ac-
celeration.

Among the numerous inequalities which affect the motion of the moon, one still remained which no philosopher as yet had been able to explain. This was the acceleration of the mean lunar motion, which had been first suspected by Dr Halley, from a comparison of the ancient Babylonian observations, recorded by Hipparchus, with those of Albategnius and the moderns. The existence of the acceleration had been confirmed by Dunthorne and Mayer, and its quantity assigned at $10''$ in a century, but the cause of it remained doubtful. Lagrange demonstrated that it could not be occasioned by any peculiarity in the form of the earth; Bossut ascribed it to the resistance of the medium in which he supposed the moon to move; and Laplace himself at first explained it on the supposition that gravity is not transmitted from one body to another instantaneously, but successively in the manner of sound or light. Having afterwards remarked, however, in the course of his researches on Jupiter's satellites, that the secular variation of the eccentricity of the orbit of Jupiter occasions a secular variation of the mean motions of the satellites, he hastened to transfer this result to the moon, and had the satisfaction to find that the acceleration observed by astronomers is occasioned by the secular variation of the eccentricity of the terrestrial orbit. This was the last celestial phenomenon which remained to be accounted for on the principle of gravitation.

Inequali-
ties of Ju-
piter and
Saturn.

Another discovery relative to the constitution of the planetary system, which does infinite honour to the sagacity of Laplace, is the cause of the secular inequalities indicated by ancient and modern observations in the mean motions of Jupiter and Saturn. On examining the differential equations of the motions of these planets, Laplace remarked, that as their mean motions are nearly commensurable (five times the mean motion of Saturn being nearly equal to twice that of Jupiter), those terms of which the arguments are five times the mean longitude of Saturn, minus twice that of Jupiter, may become very sensible by integration, although multiplied by the cubes and products of three dimensions of the eccentricities and inclinations of the orbits. The result of a laborious calculation confirmed his conjecture, and showed him that in the mean motion of Saturn there existed a great inequa-

lity, amounting at its maximum to $48' 2\frac{2}{3}$, and of which the period is 929 years; and that in the case of Jupiter there exists a corresponding inequality of nearly the same period, of which the maximum value is $19' 46''$, but which is affected by a contrary sign, that is to say, diminishes while the first increases, and *vice versa*. He also perceived that the magnitude of the co-efficients of these inequalities, and the duration of their periods, are not always the same, but participate in the secular variations of the elements of the orbits.

History.

The theory of the figures of the planets, scarcely less interesting than that of their motions, was also greatly advanced by the researches of Laplace. He confirmed the results of Clairaut, Maclaurin, and D'Alembert, relative to the figure of the earth, and treated the question in a much more general way than had been done by those three great mathematicians. From two lunar inequalities depending on the non-sphericity of the earth, he determined the ellipticity of the meridian to be $\frac{1}{305}$ very nearly.

Figure of
the earth.

Newton, in the *Principia*, explained the cause of the Tides. phenomena of the tides, and laid the foundations of a theory which was prosecuted and extended by Daniel Bernoulli, Maclaurin, Euler, and D'Alembert; but as no one of these geometers had taken into account the effects of the rotatory motion of the earth, the subject was in a great measure new when it was taken up by Laplace in 1774. Aided by D'Alembert's recent discovery of the calculus of *Partial Differences*, and by an improved theory of hydrodynamics, he succeeded in obtaining the differential equations of the motion of the fluids which surround the earth, having regard to all the forces by which these motions are produced or modified, and published them in the Memoirs of the Academy in 1775. By a careful examination of these equations, he was led to the curious remark, that the differences between the heights of two consecutive tides about the time of the solstices, as indicated by Newton's theory, are not owing, as Newton and his successors had supposed, to the inertia of the waters of the ocean, but depend on a totally different cause, namely, the law of the depth of the sea, and that it would disappear entirely if the sea were of a uniform and constant depth. He also arrived at the important conclusion, that the fluidity of the sea has no influence on the motions of the terrestrial axis, which are exactly the same as they would be if the sea formed a solid mass with the earth. The same analysis conducted him to the knowledge of the conditions necessary to insure the permanent equilibrium of the waters of the ocean. He found that if the mean density of the earth exceeds that of the sea, the fluid, deranged by any causes whatever from its state of equilibrium, will never depart from that state but by very small quantities. It follows from this, that, since the mean density of the earth is known to be about five times greater than that of the sea, the great changes which have taken place in the relative situation of the waters and dry land must be referred to other causes than the instability of the equilibrium of the ocean.

Closely connected with the problem of the tides is that of the precession of the equinoxes, which also received of the equinoxes. similar improvements in passing through the hands of Laplace. He demonstrated, as has just been mentioned, that the fluidity of the sea has no influence on the phenomena of precession and nutation. He considered some of the effects of the oblate figure of the earth which had not been attended to by D'Alembert, and showed that the annual variation of the precession causes a corresponding variation in the length of the tropical year, which at present is about 9 or 10 seconds shorter than it was in the time of Hipparchus. He proved that the secular inequa-

History. lities of the motions of the earth and moon have no sensible effect in displacing the axis of the earth's rotation; and he determined the nutation of the lunar orbit corresponding to the nutation of the terrestrial equator.

Jupiter's satellites. Physical astronomy is also indebted to Laplace for a complete theory of the system of Jupiter's satellites, from which Delambre constructed a set of tables which represent the motions of these bodies with all desirable accuracy. And when to these numerous and most important researches we add the mathematical theories of molecular attraction, and the propagation of sound, together with many great improvements in analysis,—and reflect, besides, that he is the author of the *Mécanique Céleste*, the *Système du Monde*, and the *Théorie des Probabilités*,—we shall not hesitate to rank him next to Newton among the greatest benefactors of the mathematical and physical sciences.

By the brilliant discoveries of Laplace, the analytical solution of the great problem of physical astronomy was completed. The principle of gravity, which had been discovered by Newton to confine the moon and the planets to their respective orbits, was shown to occasion every apparent irregularity, however minute, in the motions of the planets and satellites; and those very irregularities which were at first brought forward as objections to the hypothesis have been ultimately found to afford the most triumphant proofs of its accuracy, and have placed the truth of the Newtonian law beyond the reach of all future cavil. Such is the state to which analysis has now attained, that the geometer embraces in his formulæ every circumstance which affects the motions or positions of the different bodies of the planetary system; and the conditions of that system being made known to him at any given instant of time, he can determine its conditions at any other instant in the past or future duration of the world. He ascends to remote ages to compare the results of his theories with the most ancient observations; he passes on to ages yet to come, and predicts changes which the lapse of centuries will hardly be sufficient to render sensible to the observer. But notwithstanding the proud elevation to which the theory of astronomy has been raised, it is still far from having reached the limit beyond which further refinement becomes superfluous. The masses of the planets, and some other elements, remain to be determined with still greater precision, by a diligent comparison of the analytical formulæ with good observations; and the labours of the geometer may still be beneficially employed in giving greater simplicity to the calculus, or in extending its power over subjects which have hitherto eluded its grasp. The recent discovery of two periodic comets completing their revolutions in comparatively short intervals of time, opens up an interesting field for speculation and research, and will doubtless be the means of throwing light over some curious, and as yet very obscure, points, respecting the appearances, motions, and physical constitution of those strange bodies.

In the other departments of the science, also, numerous questions still remain to be discussed, the solution of which will occupy and reward the future labours of the astronomer. The curious phenomena of double and multiple stars, some of which appear to form connected systems of bodies revolving about one another, or a common centre of motion,—the variable stars,—the proper motions of the stars,—the translation of the solar system in space,—the progressive condensation of nebulae,—are subjects still in a great measure new; for it is only of late years that observers have begun to direct the requisite attention towards them, or indeed have been in possession of instruments of sufficient power and delicacy to observe and measure the minute changes which take place beyond the

boundaries of our own system. The observations of some living astronomers, particularly of Mr Herschel and Mr South, have made known some important facts regarding the nebulae and double-stars, and laid the foundations of interesting discoveries to be realized by their successors in future ages of the world.

Among the events auspicious to the future progress of astronomy in our own country, we cannot forbear to regard the establishment of the *Astronomical Society of London*, an association which, though it dates only from 1820, includes in its list of *Members* the names of the greater part of the most distinguished cultivators of the science in Europe. The society has already given the best proofs of its energy and usefulness, by the publication of a catalogue of the reduced places of 2881 of the principal stars visible above our horizon, and four splendid volumes of *Memoirs*, replete with information and remarks of the most useful kind to the observer. The number of public observatories recently established, or at present in a state of progress, in various parts of the country and its colonies, also holds out a cheering prospect to the friends of astronomical discovery. Nor if we turn our eyes abroad shall we perceive less reason for congratulation. The same zeal for extension and refinement is manifested in every country of Europe; and while some of the states, among which Prussia and Denmark deserve to be honourably mentioned, are gaining themselves glory by the encouragement they hold out to the cultivation of this department of science, the exertions of individual observers appear to increase in proportion as the field is narrowed by their success. Armed with instruments to which former times had nothing to compare, the astronomer of the present day not only anticipates a more perfect knowledge than he yet possesses of the nature and number of the bodies belonging to the solar system, but aspires to set at rest the disputed question of parallax, to determine the proper motions of the stars, and trace the effects of gravity in the remotest regions of the universe.

Such are the present prospects of astronomy. The mind delights to contemplate unlimited advancement in a walk in which its efforts have been so signally triumphant; yet in consequence of what has already been done, the future progress of the science must necessarily be slow; and it must be acknowledged that greater precision than has already been attained is unnecessary to navigation or geography, or any practical application of which astronomy admits. The future results of observation may add to the stock of speculative knowledge, but can only be remotely useful to mankind.

The following works may be consulted on the history of Works on astronomy:—Riccioli, *Almagestum Novum*, Bononiæ, 1653, the history of 2 vols. folio; Sherburn's *Translation of the Astronomicum* of Manilius, London, 1675; Weidler, *Programma de Veteris et Novæ Astronomiæ Discrimine*, Wittembergæ, 1720; Souciet, *Observations Mathématiques, Astronomiques, &c.* 1729, 2 vols. 4to. The second volume of this work, by Gaubil, contains a history of the Chinese Astronomy, with Disquisitions. These six volumes of Delambre's *Histoire* contain copious extracts of all the principal works which have been published on the subject of astronomy, interspersed with much enlightened criticism.

PART II.

THEORETICAL ASTRONOMY.

CHAP. I.

GENERAL PHENOMENA OF THE HEAVENS.

SECT. I.—Of the Celestial Sphere.

WHEN a spectator on a clear evening directs his attention to the sky, he perceives a concave hemisphere studied with innumerable brilliant points, all which appear to move in parallel directions, constantly preserving the same distances and relative positions. New groups of stars incessantly follow one another, rising in the east, mounting to a certain height, and then gradually sinking till they disappear in the west. On turning his face towards the north he observes some groups of stars which remain visible during the whole night; wheeling round a certain fixed point, and describing circles of greater or less magnitude, according as they are at a greater or less distance from that point. The same phenomena are observed every successive night; and as the stars present always the same configurations, and succeed each other in the same order, the mind is irresistibly led to the hypothesis of the diurnal revolution of the whole heavens about a fixed axis. This hypothesis implies that the stars move in parallel planes, and that their mutual distances remain invariable. In order, however, to be assured that such is the case, it is necessary to have recourse to more accurate observations, and to refer their successive positions to something that is fixed,—to certain points or planes which do not participate in the general motion.

Horizon.

What is most obviously adapted for this purpose is the *Horizon*, or the plane which appears extended all round us, and bounded by a circle of which the eye of the spectator occupies the centre. Let the circle SENW (fig. 1) represent the horizon, C being the centre or place of the observer. Suppose now that a star is observed to rise at a certain point of the horizon A, and, after tracing its circuit in the sky, to set at the point A'; suppose, also, that another star rises at B, and sets at B'; then, if the distances AB, A'B' are measured by means of some angular instrument, it will be found that AB is equal to A'B', and that this is the case with regard to any two stars whatever. Since therefore the arcs AB and A'B' are equal, it follows that the chords AA', BB', joining their extremities, are parallel; whence we infer, that if two stars rise successively at the same point of the horizon A,

they will also set at the same point A', a circumstance which is of itself strikingly indicative of the uniformity of the motion of the celestial bodies.

Through C let a perpendicular be drawn to the chord AA', meeting the boundary of the horizon in S and N. These two points are the *South* and *North* points of the horizon; and another straight line drawn through C, parallel to A A', will meet the horizon in E and W, the *East* and *West* points. The four together, namely, S, E, N, W, are called the four *Cardinal* points of the horizon. The horizontal circle is itself denominated the *Azimuth Circle*. Azimuth distances are measured from the North and South points, so that SA is the azimuth distance of a star's rising at A, and SA' is that of its setting at A'. The complement of the azimuth, or its defect from a right angle, is called the *Amplitude*, which is consequently measured from the East and West points; thus the arc EA is the amplitude of a star's rising at A, or its *ortive* amplitude, and WA' is that of its setting, or its *occasive* amplitude.

Conceive a straight line to pass through C, perpendicular to the horizon. This line, which is called the *Vertical*, will meet the visible hemisphere in a point directly above the observer, which is denominated the *Zenith*; the point diametrically opposite, in which the prolongation of the vertical meets the invisible hemisphere, is the *Nadir*. The plane determined by the vertical and the straight line NS is called the *Meridian*, because when the sun reaches it, he is equally distant from the points at which he rises and sets, or, it is mid-day. The great circle formed by the intersection of the meridian with the celestial sphere is the *Meridional circle*; it divides the sphere into the eastern and western hemispheres. Any circle passing through the Zenith and Nadir is called a *Vertical Circle*; that which intersects the meridional circle at right angles, or which passes through the points E and W, is called the *Prime Vertical*.

Let HPZH' (fig. 2) represent a meridional circle passing through P, that point of the sphere which appears to remain immovable; and let Z be the zenith, and HH' the horizon. Join PC, and let it meet the circle in P'. The points P and P' are denominated the *Poles* of the world, and the straight line PP' is the *Axis* about which the whole heavens appear to revolve. Let also *uv*, *Hg*, *hl*, *ÆE*, *g'H*, be projections of the paths of different stars

Plate
LXXIX.
Fig. 1.

Fig. 2.

on the vertical plane PZH. One of the first circumstances which strikes the attention of the observer is the inequality of the times during which different stars continue visible above the horizon. A star which describes the circle $\mathcal{A}\mathcal{E}$ continues visible during a shorter time than one which describes hl , and still shorter than one which moves in Hg . It will be remarked, however, that the interval between two successive risings of the same star is always the same, in whatever point of the horizon it makes its appearance. Those which describe $\mathcal{A}\mathcal{E}$ are peculiar in this respect, that the interval between their rising and setting is exactly equal to that between their setting and rising; hence the great circle which they describe is called the *Equator*, and when the sun describes that circle, the days and nights are exactly of the same length. In general, the time during which a star continues visible is greater in proportion as its path is nearer to the visible pole. Those, however, which describe the circle Hg , or any other parallel, as uv , nearer to P , remain always above the horizon; hence such circles are called circles of *Perpetual Apparition*, and the stars describing them are called *Circumpolar Stars*.

There are some other technical terms, chiefly employed in the old treatises of astronomy, to denote particular circles of the sphere. A *Secondary* to any great circle, is a circle passing through the poles of its primary: thus the meridian is a secondary to the horizon HH' , and to the equator $\mathcal{A}\mathcal{E}$. The *Colures* are two secondaries to the equator, one of which passes through the equinoctial points, and is called the *Equinoctial Colure*; the other intersects the equator at the distance of 90° from the former, and is denominated the *Solstitial Colure*. The small circles parallel to the equator are simply termed *Parallels*; those which are parallel to the horizon are called *Almicantars*; and the different meridians are likewise termed *Hour Circles*.

The hypothesis of a spherical revolution implies, as has already been mentioned, that the stars move in parallel planes, or describe parallel circles round the pole. This point, in reference to any particular star, must be determined by observing whether its angular distance from the pole remains invariable during its whole revolution. Let Z (fig. 3) be the zenith, P the pole, and S the place of a star. The arcs PZ , ZS , PS , which join these points on the sphere, will form a spherical triangle, of which the sides PZ and ZS , or the distances of the pole and the star from the zenith, are given by direct observation. The angle PZS is also given in the same manner, for it is equal to the star's azimuth counted from the north point of the horizon. In the triangle ZPS we have therefore given the two sides ZP and ZS , together with the included angle PZS , from which data the polar distance PS is found by the following formula of spherical trigonometry:

$\cos. PS = \sin. ZS \sin. ZP \cos. PSZ + \cos. ZS \cos. ZP$.
In order to adapt this formula to logarithmic computation, an auxiliary angle ϕ may be assumed such, that $\tan. \phi = \cos. PZS \tan. ZP$, by the substitution of which the formula becomes

$$\cos. PS = \frac{\cos. ZP \cdot \cos. (PZS - \phi)}{\cos. \phi};$$

from which the polar distance PS of the star can be easily computed.

On performing the computation for any particular star, PS is always found to be of a constant magnitude, whatever may be the value of PZS , that is, at whatever part of its course the star is observed. Hence we infer that the diurnal motion of the stars round the pole is exactly circular.

After having recognised that the celestial bodies move in parallel planes, the next object of the astronomer is to determine whether they revolve with velocities uniform or variable. For this purpose it is necessary to compare, by means of a well-regulated clock, the angular distances between the meridian and the successive positions of a star, with the times elapsed since the star's passage over the meridian. Let mno (fig. 4) be the parallel described by a star, and ss' two of its successive positions. The arcs ns , ns' , intercepted between the meridional plane and the planes passing through the axis PP' and the points s , s' , are measured by the arcs of the equator Ca , Cb . Now, it is the result of constant experience, that the number of degrees in the arc Ca or Cb is to the number in the whole circumference as the time employed by the star in describing na or nb is to the time in which it completes a revolution. The time occupied by the star in completing its revolution is called a sidereal day; and the uniformity of the diurnal revolution enables us to calculate the angle CPs , which is measured by Ca , without having recourse to any other observation than that of the star's meridional passage. Denoting a sidereal day by T , the interval of time which elapses while the star describes the arc ns by t , and the angle at the pole by P , we shall have the analogy $T:t::360:P$; therefore $P=360^\circ \frac{t}{T}$;

a formula which gives the angle at P , or its measure Ca . The angles CPs , CPs' , and sPs' are called *Hour Angles*, because the arcs which they intercept on the star's parallel of declination correspond to the hours and fractions of an hour into which the sidereal day is divided. For example, if the hour angle sPs' contain 15° , the two planes passing through s and s' will intercept on mn , the diurnal circle of the star, an arc equal to 15° ; consequently there will be 24 such arcs in the whole circumference, each of which will be described in the 24th part of a sidereal day, or in one hour of sidereal time. In consequence of this perfect uniformity of the diurnal motion, the arc which a star describes on its parallel is conveniently measured by the time of its description; and the sidereal day, or the interval between two successive returns of the same star to the plane of the meridian, offers the most perfect *unit of time*, inasmuch as it is exactly the same to all the inhabitants of the earth, and remains absolutely unalterable in all ages, being one of the very few invariable elements of the system of the world.

In fixing the position of a point on a plane surface, geometers usually refer it to two straight lines at right angles to each other, the positions of which are supposed to be known. The same practice is imitated by astronomers, who refer the position of any point on the surface of the sphere to two great circles, which are employed as a system of rectangular co-ordinates, and from which all distances are measured. The equator being a circle of the sphere not subject to any arbitrary condition, but determined by the very nature of the spherical revolution, is obviously well adapted for this purpose. It is therefore universally employed as a term of comparison in assigning the places of the celestial bodies. Suppose an hour circle passing through the star s to intersect the equator at a ; the arc sa , which measures on the sphere the distance of s from the equator, is called the *Declination* of the star. All other stars situated on the same parallel mo have the same declination; and it is invariable for all places of the earth, because it is not affected by the diurnal motion which is performed in the parallel mo . The declination is *northern* or *southern*, according as the star is situated in the northern or southern hemisphere. It is expressed in degrees from 0 to 90, proceed-

Theoretical Astronomy.

Hour angles.

Method of determining the situations of points on the sphere.

Fig. 4.

Declination.

Theoretical ing from the equator to the pole. The polar distance *Ps* is the complement of the declination, because $Ps + sa = 90^\circ$. In order to distinguish *s* from all other stars which may be situated on the same parallel, we must also know the point *a* of the equator to which it corresponds; and for this purpose it is necessary to select a point γ of the equator for the origin of the co-ordinates. This point ought to be independent of the diurnal motion, otherwise its position could only be determined for a single instant of time; and it must be such that it can be readily found, in whatever part of the earth the observer may be situated. Astronomers have agreed to employ for this purpose the point determined by the intersection of the equator with another very remarkable circle of the sphere, of which we shall speak hereafter, and to count the degrees on the equator, setting out from γ , from 0 to 360, in the direction opposite to that of the diurnal motion, or from west to east. The arc γa , which measures the distance between γ and *a*, is called the *Right Ascension* of the star *s*: it is also the right ascension of any other star situated in the hour circle *PsP'*. It is measured by the interval of time which elapses between the transit of the star *s* over the meridian, and that of the point γ , which has been chosen as the point of departure. It may be remarked that the point γ is also the origin of sidereal time; that is to say, the time is counted 0 hour 0 min. 0 sec. when that point passes the meridian.

Right ascension.

From these definitions it is easy to conceive the general method of forming a catalogue of stars. A clock being regulated to sidereal time, and marking 0 hour at the instant of the transit of the point γ (or any star chosen arbitrarily), the hours, minutes, and seconds, are noted at which the stars successively pass the axis of the transit instrument, together with their respective altitudes at the same instant. These observations give the right ascensions and declinations; for the time is easily converted into degrees, at the rate of 15° an hour, or by the formula given above for determining the hour angle. If the star *s* pass the meridian one hour after *s'*, the arc *a b*, which measures the distance between their horary circles, *PaP'*, *PbP'*, is 1 hour or 15° ; and the declination of a star *s* which moves in the parallel *kl* (fig. 2) is $El = H'l - H'E$, that is, equal to the difference between its meridional altitude and the complement of the altitude of the pole *H.P*. Modern celestial charts are constructed on the principle of assigning to each star the place indicated by the values of these two co-ordinates; and as observation proves that the mutual distances and relative positions of the stars scarcely undergo any sensible variation, a globe or chart once constructed will serve to represent the state of the heavens for at least a long series of ages.

Fig. 2.

Explanation of the phenomena.

Having now considered the general phenomena of the diurnal revolution, and explained the terms that are technically employed in assigning the positions of the celestial bodies, we may next proceed to inquire how these phenomena are to be accounted for,—whether the stars are really in motion, as they seem to be, or if the apparent motion is only an illusion occasioned by the revolution of our own earth. The perfect uniformity of the motions of the different stars renders it exceedingly improbable that they are disconnected; hence the simplest view of the phenomena is obtained by substituting for each star its projection on the celestial sphere, at an infinite distance, and supposing this sphere, with the projections of all the stars, to revolve in 24 hours from east to west round an immovable axis. But it is easy to see that the phenomena will be equally well explained by supposing that the starry firmament is absolutely at rest, and that

the earth revolves in the same time, round the same axis, but in an opposite direction, from west to east. In both cases the stars remain immovable, the phenomena are exactly the same, and, relatively to *Spherical Astronomy*, in which we only concern ourselves with the apparent motions, it is absolutely indifferent which of the two hypotheses we adopt. They are both only modes of explaining certain appearances; and the one may be employed which renders the explanation most simple and perspicuous. The proofs of the earth's motion will go on accumulating as we proceed. At present we need only remark, that as the organ of sight makes us acquainted with the existence of relative, and not of absolute motion, it is impossible to decide, merely from appearances, whether the motion we perceive is real or otherwise; for whatever motion one body may have in respect of another, it is always possible to explain the phenomena by supposing it to be perfectly at rest, and the other to move in an opposite direction. The conclusions which we draw from the optical effects of motion afford no mathematical certainty with regard to the cause of that motion. The hypothesis of the revolution of the sphere is attended with innumerable and insurmountable difficulties. The distance of the nearest fixed star from the earth is not less than 350,000 times the distance of the sun; a distance which light, prodigious as its velocity is, would not traverse in less than five years. This immense line, therefore, supposing the heavens to revolve round the earth, would form the radius of a circle, the circumference of which, six times larger, would be passed over by the star in the space of 24 hours; its velocity must therefore be $6 \times 5 \times 365 = 10950$ times greater than that of light. This velocity, which is nearly equivalent to 2100 millions of miles in a second of time, is so enormous that it baffles the utmost efforts of the imagination to form any conception of it; and the supposition of its existence will appear still more revolting when we reflect that the distance of the nearest star is probably many thousand times less than that of the Milky Way. If we ascribe the motion to the earth, its velocity, though it may still be supposed great, is moderate in comparison of many well-known phenomena of nature. A point on the equator will describe in 24 hours a circle of about 25,000 miles, or about 17 miles in a minute; a velocity somewhat exceeding that of sound, but 7400 millions of times less rapid than the preceding.

In all that has hitherto been said respecting the apparent motion of the starry sphere, we have only had regard to the innumerable multitude of stars which constantly maintain the same relative situations, and which are in consequence called *Fixed Stars*. There are, however, several other bodies, some of them remarkable on account of their splendour, which, besides participating in the general motion, have peculiar motions of their own, and are incessantly shifting their positions among the fixed stars. An attentive observation of the state of the sky during a few successive evenings, will suffice to show that there are some stars which have in the mean time changed their places; and, on continuing to observe them, they will be found to separate themselves from particular constellations, and gradually but imperceptibly to approach others, till they at length appear, after unequal intervals of time, in an opposite quarter of the heavens. From this circumstance they were designated by the Greeks *Planets*, that is, *wandering stars*, in contradistinction to those which obey only the law of the diurnal motion. Besides the sun and moon, there are five discernible by the naked eye, and which have consequently been known from the remotest ages. These are Mercury, Venus, Mars, Jupiter, and Saturn. Five others, namely, Uranus, Ceres, Pallas, Juno,

Theoretical and Astronomy. scope. Astronomers, with a view to abbreviate their descriptions, have appropriated a certain symbol to each of these planets, as well as to the sun and moon: thus, in the order of distance from the sun, the names and characteristics are as follows:—

The Sun.....☉	Ceres.....♄
Mercury.....☿	Pallas.....♂
Venus.....♀	Jupiter.....♃
Mars.....♂	Saturn.....♄
Vesta.....♁	Uranus.....♅
Juno.....♁	

The Earth, which, as we shall afterwards see, is also a planet, and takes its place between Venus and Mars, has for its symbol ⊕, and the moon ☾. Venus, Jupiter, and sometimes Mars, are distinguished by their extraordinary brilliancy. Mercury, on account of his proximity to the sun, is rarely visible to the naked eye. Uranus, discovered by Sir W. Herschel in 1778, can with difficulty, by reason of his great distance, be perceived without a telescope. Ceres, Pallas, Juno, and Vesta, discovered since 1801, are extremely small in size, and can only be seen with the aid of the telescope.

Of all the celestial bodies, the most interesting to us are the sun and moon; and their peculiar motions have accordingly, in every age of astronomy, been studied with the greatest attention. The proper motion of the moon is particularly remarkable. In the course of a single night she separates herself very sensibly from the stars in her vicinity, moving over a space nearly equal to her own breadth in an hour, and completing a whole circuit in about 27 days. The sun moves with much less velocity, but his motion is still sufficiently apparent. If we take notice of the stars which immediately follow him when he sinks under the horizon, we shall find that in the course of a few nights they will be no longer visible. Others which, some time previously, did not set till long after him, have taken their places and now accompany the sun. In the morning similar appearances present themselves, but in a contrary order. The stars which appear in the eastern horizon at sun-rise, are, after a few days, considerably elevated above it at the same time. Thus the sun seems to fall daily behind the stars, by insensible degrees, till at last he appears in the east when they are about to set in the west. To account for these appearances, the ancients supposed the sun's diurnal motion to be really slower than that of the stars; hence they supposed him to be attached to a different sphere. For like reasons they ascribed particular spheres to the moon and each of the planets; and as no trace of these imaginary spheres is perceptible in the heavens, they next supposed them to be crystalline and transparent. The appearances are explained equally well, and with infinitely greater simplicity, by ascribing to the sun a proper motion, in a direction opposite to that of the diurnal rotation of the sphere, in consequence of which he advances to meet the stars, instead of falling behind them.

The greater part of the observations of the early astronomers had for their object the determination of the positions of the stars relatively to the sun at his rising and setting, by which they fixed the seasons, and regulated the operations of agriculture. They distinguished all these phenomena by technical terms, which occur very frequently in the works of the ancient poets, particularly in Hesiod and in Ovid's *Fasti*. A star which rises at the same time with the sun is effaced by his light, and is said to rise *cosmically* (*ortus cosmicus*). Soon after, when the sun by his proper motion has advanced so far to the east that the star can be perceived on the eastern horizon in

the morning twilight, it disengages itself from the sun's rays, and is said to rise *heliacally* (*ortus heliacus*). At the end of six months, the sun being diametrically opposite to the same star, it sets as the sun rises, and in this case it is said to set *cosmically* (*occasus cosmicus*): at nearly the same time it rises when the sun sets, and is said to rise *acronically* (*ortus acronyctus*). The sun afterwards begins to approach the star, till he advances so near that it is again about to be effaced by his light; it is now said to set *heliacally*, or just so long after the sun as to be visible when he has disappeared (*occasus heliacus*). At the end of a year, the star again rises and sets at the same moment with the sun; it is now said to set *acronically* (*occasus acronyctus*). These distinctions, and the ancients had several others of the same kind, which are all defined by Ptolemy, are now scarcely ever mentioned. They have lost the whole of their interest since, in the progress of astronomy, more certain methods have been discovered of determining the commencement of the year and the seasons.

The proper motions of the planets are in general, like Stations that of the sun, in a direction opposite to the diurnal motion, or from west to east, among the stars: but they do not preserve the same character of uniformity; the planet sometimes becomes stationary among the fixed stars, and even advances from east to west in the direction of the diurnal motion. In this case it is said to *retrograde*. This retrograde motion is, however, not of long continuance. After having been accelerated during a short time, it begins to relax. The planet again becomes *stationary*, and then resumes its *direct* motion from west to east. These phenomena were observed in the remotest antiquity, and their explanation formed the principal part of the rational astronomy of the Greeks and the Arabians.

Besides the planets, other bodies occasionally make their appearance in the heavens, which, by reason of the extraordinary phenomena they exhibit, have been frequently contemplated with terror and dismay, and regarded by superstitious ignorance as harbingers of calamity, and precursors of the divine vengeance. These bodies shoot down, from the remote regions of space, with inconceivable velocity, towards the sun. At their first appearance they are small; their light is feeble and dusky; and they are generally accompanied by a sort of nebulousity or luminous tail, from which they have derived their appellation of *Comets* (*coma*, hair). As they approach the sun, their apparent magnitudes and brilliancy greatly increase, and the nebulousity sometimes occupies a large portion of the heavens, presenting a magnificent and astonishing spectacle. Having attained the point of their orbits nearest the sun, they again recede to enormous distances, and vanish by insensible degrees. They differ from the planets not only by the appearances they present, but also by the diversity of their motions; for, instead of being confined to a particular zone, and moving from west to east, they traverse the sky indifferently in all directions. They are visible only in a small part of their orbit, which, being near the sun, is passed over with prodigious rapidity. They seldom continue visible longer than six months. Their number is entirely unknown, but during the last two centuries upwards of 150 have been observed, and their orbits computed.

Thus we recognise three distinct classes of celestial bodies; the planets, the comets, and the fixed stars. It is the business of the astronomer to determine the positions of these bodies in the heavens; to observe their motions, and measure them with precision; to discover the laws by which their courses are regulated; and from these laws to assign the past or future state of the heavens

Theoretical
Astronomy.

at any given instant of time. The fixed stars form infinitely the most numerous class; but their motions being sensibly uniform, and their mutual distances invariable, the principal object with regard to them is to determine their places and relative positions. The comets in general return only after long periods; and observations are not yet sufficiently numerous to allow any certain deductions to be made with respect to their nature and constitution. The planets present a great variety of curious phenomena; they are always within our view; observations on them may be multiplied indefinitely; and for this reason, as well as on account of their proximity, and their forming a system of which the earth constitutes a part, they present by far the most interesting objects of astronomical study.

SECT. II.—Of the Globular Form of the Earth, Parallax, and Refraction.

Having now considered the general phenomena of the diurnal motion, we proceed next to inquire into the form of the earth, and our situation with respect to the centre round which the celestial sphere appears to revolve. The plane of the horizon seems to be stretched out indefinitely till it actually meets the sky; but this illusion is quickly dissipated by transferring ourselves from one place to another on the surface of the earth, and attending to the phenomena which such a change of place gives rise to. Let an observer, for example, set out from any given point in the northern hemisphere, and proceed directly south. In proportion as he advances, the stars in the southern region of the heavens will be elevated more above the horizon, and describe larger segments of their diurnal circles, while new ones come into view which were invisible at the station he left. On the other hand, the polar star, with those in its vicinity, will be depressed, and some stars which before continued above the horizon during the whole time of their revolution will now rise and set. The planes of the diurnal circles become also more perpendicular to the horizon, so that the aspect of the heavens is entirely changed. If, instead of advancing in the direction of the meridian, the spectator proceeded towards the east or west, he would in this case also remark that his horizon constantly shifted its position. A star will pass his meridian sooner as he advances eastward, or later as he travels westward; in short, by a change of place in any direction whatever, the perpendicular to the horizon, or the plumb-line, will correspond to a different point of the heavens. The plane of the horizon is therefore variable, and its variation by insensible degrees indicates with the greatest evidence the rotundity of the earth. Experience also shows that a spectator sees more of the terrestrial surface in proportion as he is elevated above it; and that on a mountain surrounded by the sea, or standing in the middle of a level plain, the horizon appears equally depressed all round, which is the distinctive feature of a spherical curvature. In fig. 5 let O be the place of a spectator on the summit of a mountain, the straight line H H will represent his horizon, and Oh, OH' the directions of visual rays to the remotest visible points on the surface of the earth. The inclinations of these lines to the plane of the horizon, or the angles HOh, H'O'h' are called the *apparent depression*; and these being always observed to be equal to each other, it follows that the curve hAh' is a circle. On the Peak of Teneriffe, Humboldt observed the surface of the sea to be depressed on all sides in an angle of nearly 2°. The sun arose to him 12 minutes sooner than to an inhabitant of the plain; and from the plain, the top of the mountain appeared enlightened 12 minutes before the rising or after the setting of the sun. The same phenomena, though on a smaller

Fig. 5.

scale, are observed with regard to every mountain or elevation on the earth. Another familiar illustration of the globular figure of the earth is derived from the successive and gradual disappearance of a ship which leaves the shore and stands out to sea. The hulk disappears before the sails and the rigging, and the top of the mast is the last part that is visible. The ship thus appears gradually to sink under the horizon, exactly in the same manner as she must necessarily do on the supposition that the surface of the sea is spherical. The appearance of the moon at the time she is eclipsed is also demonstrative of the roundness of the earth. When the moon penetrates the shadow of the earth, the line which separates the illuminated from the eclipsed portion of the disk is circular; evidently proving the conical form of the shadow, and consequently the roundness of the body by which the shadow is projected. From all these considerations, it is inferred with the highest certainty that the earth with its waters forms a round mass, isolated in space.

The globular form of the earth is a property common to it with the other bodies which compose the planetary system. The sun and moon are evidently round bodies; and when the planets are examined through a telescope their disks appear sensibly circular; and as they are known to have a motion of rotation, in consequence of which they successively present different points of their surfaces to the earth, the uniform roundness of their disks may be taken as a conclusive proof of their sphericity. We shall by and by have occasion to remark other striking analogies between the planets and the earth.

Since the figure of the earth is spherical, the horizontal plane cannot coincide with any considerable portion of its surface. It may be defined to be the plane which touches the earth at any given point, and is perpendicular to the vertical line, or the direction of gravity at that point. The *Sensible Horizon* of any place is the plane which passes through the eye of the spectator, perpendicular to the plumb-line at that place. The *Rational Horizon* is a plane parallel to this, passing through the centre of the earth. The particular phenomena of different places depend on the position of their horizon with respect to the planes of the apparent diurnal motion of the sun and stars. The rational horizon of a place on the equator passes through the poles, and divides equally the equator and its parallels. Hence the days and nights are always equal in such places, and each of the stars performs one half of its revolution above, and the other below its horizon. The circles of diurnal motion are all perpendicular to the horizon, and therefore the inhabitants are said to be under a *Right Sphere*. If a spectator could place himself directly under the pole, his horizon would coincide with the equator, and the whole of the northern celestial hemisphere would be within his view, while no part of the southern hemisphere would be visible to him, on account of its being always beneath the horizon. The circles of the diurnal motion being parallel to the equator, and consequently also to the horizon, the fixed stars would never either rise or set. A spectator thus situated is said to be under a *Parallel Sphere*. In intermediate places the circles of the diurnal motion are oblique to the horizon, one pole being always elevated above it, and the other equally depressed below it. The stars whose distances from the elevated pole are not greater than the arc of its elevation above the horizon never set, while those within the same distance of the depressed pole never rise. These phenomena belong to all places situated between the equator and the poles, and the inhabitants of such places are said to be under an *Oblique Sphere*.

The situation of a place on the surface of the earth is determined by two co-ordinate circles, in the same manner as that of a star on the celestial sphere. Let Z (fig. 2) be a place of which the position is required to be assigned with reference to circles of the terrestrial sphere, analogous to those which we have described as belonging to the sphere of the heavens. Since the axis of the celestial sphere passes through the centre of the earth, we may suppose the poles of the world, the equatorial circle, and the meridians, to be transferred to the earth's surface, so that the same figure may represent either the celestial or terrestrial sphere. The intersection of the plane PZÆ with the surface of the earth is the terrestrial meridian of the place Z, and the straight lines CZ, CÆ, in that plane, intercept an arc of the terrestrial meridian between Z and the equator, containing as many degrees as the arc of the celestial sphere which measures the declination of the zenith of the place Z. The angle ÆCZ which is measured by the meridional arc ÆZ is called the *Geographical Latitude* of Z. But in order to particularize the point at which the equator is intersected by the meridian, it is necessary to assume some point of the equator to which all the other points of that circle may be referred. The meridian passing through the assumed point is called the *First Meridian*; and the angular distance between the planes of the first and any other meridian measured by the equatorial arc intercepted by these planes on the equator, is called the *Geographical Longitude* of the place through which the last meridian passes. The longitude is said to be *east* or *west*, according as the degrees of the equator are counted from the first meridian towards the east or west. It is usual to reckon the degrees towards the east, all round the globe, or from 0 to 360°. From these definitions it is evident that the geographical latitudes and longitudes are exactly analogous to the declinations and right ascensions on the celestial sphere. The first point of the terrestrial equator cannot be determined by any star or fixed point in the heavens, on account of the diurnal motion; it is therefore necessary to fix its position by means of known places on the earth; and geographers are in the habit of assuming as the first meridian that which passes through the capital city or principal observatory of their country. The choice is of no importance; for in geography, as in astronomy, what is essential to be known is only the *difference* of longitudes or meridians, in order to reduce the situation of a place, or observations which have been made at it, to any indicated meridian.

The length of the terrestrial radius is a very important element in astronomy, inasmuch as it furnishes the observer with the only scale by which he can estimate the distances of the sun, moon, and planets. On the supposition that the figure of the earth is perfectly spherical, the general principles on which its magnitude may be determined are sufficiently obvious; but the accurate determination of its actual dimensions is attended with great practical difficulties, which can only be overcome by the perfect instruments and refined science of modern times. Eratosthenes seems to have been the first who made use of astronomical methods to determine the circumference of the earth, or the length of the meridian. He remarked that, at Syene, in the Thebais, the sun on the meridian, at the time of the summer solstice, was vertical; and that at Alexandria, at the same time, its zenith distance was 7° 12'. Now let S (fig. 6) be the sun, vertical to M, and Z the zenith of Alexandria, C being the centre of the earth, and O Alexandria. The angle ZOS is the sun's zenith distance, which was observed to be 7° 12'. But ZOS = ZCS + OSC; whence,

as the angle OSC, which is extremely small on account of the sun's great distance, may be neglected in the calculation, the angle ZCS at the centre is also equal to 7° 12', and therefore the whole circumference equals

$\frac{360^\circ}{7^\circ 12'} \times \text{MO.}$ To obtain the length of the meridian, it is therefore only necessary to measure the arc MO. Eratosthenes assumed the distance between Syene and Alexandria to be 5000 stadia; hence the circumference of the earth = $\frac{360^\circ}{7^\circ 12'} \times 5000 \text{ stadia} = 250,000 \text{ stadia.}$ The

uncertainty which exists respecting the length of the Egyptian stade prevents us from deriving any precise information from this rude attempt to estimate the dimensions of the globe.

The method which has just been described takes for granted that the meridian is exactly circular,—an assumption which, even supposing the method perfect in all other respects, would lead to erroneous results, especially in an arc of so great a magnitude as seven degrees. In a small arc, of 1° for example, the error arising from the non-sphericity of the earth will be insensible; for it is certain, from the phenomena before explained, that the deviation from the spherical figure is not very considerable; and besides, whatever the nature of the meridional curve may be, it will sensibly coincide with its osculating circle, throughout the extent of an arc of 1°. It has been found by numerous and accurate experiments, that the lengths of arcs of 1° on the same meridian are longer in proportion as we advance nearer the pole. Hence, on account of the similarity of the isosceles triangles of which these arcs form the bases, their sides, or the terrestrial radii, must also be longer, and consequently the convexity of the earth is less towards the pole than at the equator. The surface of the earth is extremely irregular, even independently of the inequalities occasioned by mountains and cavities; yet it has been discovered that the meridional curves differ almost insensibly from ellipses; whence it is concluded that the figure of the earth is an ellipsoid of revolution about its shortest axis. In comparing the results of the various measurements which have been made with the formulæ belonging to the dimensions of such a body, this conclusion has been fully verified; and the lengths of the arcs, the ellipticity, the distance of the pole from the equator, and, in short, all the elements of the spheroid, have been determined. The results of theory and observation give an ellipticity amounting very nearly to $\frac{1}{306}$; that is to say, the equatorial is to the polar diameter in the ratio of 306 to 305. The following may be regarded as a very near approximation to the dimensions of the earth in English miles:—

Semidiameter of the equator.....	3963.7
Semidiameter of the pole.....	3949.8
Semidiameter at the latitude of 45°.....	3956.2
Ellipticity $\frac{1}{306}$	13
Length of 1° of the meridian.....	69.06
Quarter of the meridian of Paris.....	6214.47

The figure of the earth is one of the most difficult and most important questions of astronomy; and as our limits will not permit us to treat it in this place with all the details which its importance renders necessary, we shall reserve, for a separate article, an account of the different geodetical operations which have been undertaken with a view to determine it, together with the development of the mathematical theory of its equilibrium. See FIGURE OF THE EARTH.

In describing the phenomena of the diurnal revolution, we have supposed the eye of the spectator to be placed

Theoretical Astronomy. in the centre of motion, on which supposition the apparent and true places of the celestial bodies will be the same. This, however, as is evident, can only be rigorously true in respect of one point of the earth's surface, and is therefore most probably not true of any. Astronomers have on this account agreed to refer all the motions to the centre of the earth; that is, to consider the centre of the earth as the centre of the celestial sphere, and to regard as the true geocentric place of a star, that at which it would appear to a spectator placed at the centre. But the spectator is necessarily placed at the surface. In order, therefore, to render observations made at different stations on the earth's surface comparable with one another, we must consider what changes will be produced in the apparent positions of the celestial bodies, in consequence of their being observed from a point not situated in the centre of motion.

Fig. 6.
Parallax.

Let O' and O (fig. 6) be two stations on the earth's surface on the same meridian, from both of which a star S is observed at the same time. As an object is always seen in the direction of the visual ray, the spectator at O will refer the star S to a certain point I on the surface of the celestial sphere, while the spectator at O' will refer it to a different point I' in the direction $O'I'$; and the difference of the apparent places I and I' depends on the magnitude of the angle OSO' , which is subtended by the chord of the arc OO' . If a third spectator could be placed at C , the centre of the earth, the same star would appear to him in the direction CS , and be referred to its true place on the sphere at Q . Now, the difference between the angles ZOS and ZCS , that is, the angle OSC , under which the radius of the earth is seen by an observer at S , is called the *parallax* of S . On account of the great distance of the fixed stars, this angle is altogether insensible with regard to them; it is, however, very sensible in the case of the moon, with regard to which it amounts to about 1° . The greatest parallax of the nearest planets does not exceed $30''$.

Fig. 7.

From the definition which has just been given, it appears that the parallax of a star is the angle comprised between two lines drawn from the star, the one to the centre of the earth, and the other to any point whatever on its surface. But it is evident, that while the distance of S from the earth remains constant, the angle OSC will vary with the angle ZOS , that is, with the distance of the star from the zenith, or its altitude above the horizon. Let OH (fig. 7) represent the horizon. It is easy to see that the angle OSC will have its greatest value when OS touches the surface of the earth, or coincides with the horizon OH , that is, when the angle $ZOS = 90^\circ$. It is equally evident that the parallax OSC vanishes entirely when the line CS coincides with CZ , that is, when the star is in the zenith of the observer at O ; hence the parallax depends on the altitude of the star, according to a law which we now proceed to determine.

Fig. 7.

In the triangle OSC (fig. 7), we have $\sin. OSC : \sin. SOZ :: CO : CS$, whence $\sin. OSC = \frac{CO}{CS} \sin. SOZ$. Let the angle SOZ , or the zenith distance of the star $= Z$, the semidiameter of the earth $OC = a$, the distance of the star $CS = r$, and the parallax $OSC = p$, we have then $\sin. p = \frac{a}{r} \sin. Z$. On account of the smallness of the angle p , which, as we have mentioned, in no case exceeds 1° , the arc may be substituted for the sine (for their difference even in an arc of 1° does not exceed $0''.18$): the above expression therefore becomes $p = \frac{a}{r} \sin. Z$;

that is to say, the parallax of a star is proportional to the sine of its zenith distance. At the zenith, $Z = 0$, therefore $\sin. Z = 0$, and the parallax vanishes: at the horizon, $Z = 90^\circ$, and $\sin. Z = 1$; the parallax, therefore, becomes equal to $\frac{a}{r}$. In this case it is at its maximum, and

is denominated the *Horizontal Parallax*; in all other cases it is called the *Parallax of Altitude*. Denoting the horizontal parallax by P , we have $P = \frac{a}{r}$, whence

$$p = P \sin. Z;$$

that is to say, the parallax of altitude is equal to the horizontal parallax, multiplied by the sine of the apparent zenith distance. It is evident that the apparent altitude SOH is always less than the true altitude SBH , by the whole amount of the parallax; the effect of the parallax is therefore to depress the object, or increase its zenith distance; hence, if θ be the apparent altitude of the star, and θ' its true altitude, θ' will be found from the equation $\theta' = \theta + P \sin. Z$.

From the above results it is manifest, that if the horizontal parallax can be by any means determined, the parallax at any other altitude will be found at the same time. The determination of the horizontal parallax is, however, attended with considerable difficulty, and various methods have been proposed and practised to ascertain its exact amount, modified by particular circumstances in the cases of the different celestial bodies. The method, however, which serves as the basis of all the others is extremely simple, and exactly analogous to that by which the distance of a remote object is determined on the surface of the earth. Suppose two observers to be stationed at the points O and O' (fig. 6), of which the latitudes are known, and which are both situated on the same meridian, and let them simultaneously observe the zenith distances of the star S ; these observations will give the angles ZOS , $Z'O'S$, whence their supplements SOC and $SO'C$ become known at the same time. A third angle of the quadrilateral figure $SOCO'$, namely OCO' , is also known, being measured by the meridional arc OMO' , the difference or sum of the latitudes of the two observers, according as they are on the same or opposite sides of the equator. The two sides also, CO and CO' , being semidiameters of the earth, are supposed to be known; every part of the quadrilateral figure is therefore determined, and its diagonal CS may be calculated by the rules of plane trigonometry. But when CS is determined, the horizontal parallax is obtained immediately from the formula $P = \frac{a}{r}$, that is, $P = \frac{CO}{CS}$. On this principle the horizontal parallax of the moon was determined by Lacaille and Lalande, the former observing at the Cape of Good Hope, and the latter at Berlin; and the parallax of Mars by Lacaille at the Cape, and Wargentin at Stockholm.

Let us suppose two lines to be drawn from the centre of a planet touching the surface of the earth in points diametrically opposite; the inclination of these two straight lines is the double of the horizontal parallax; but the same angle also measures the diameter of the earth as seen from the planet: hence the horizontal parallax of a planet is equal to the apparent semidiameter of the earth at the distance of the planet. From this consideration the true diameter, and consequently the volume, of a planet may be found by measuring its apparent diameter, that is, the optical angle under which its diameter appears when seen from the earth. Let d be the apparent, and D the true diameter of a planet; the angle $\frac{1}{2}d$ is comprised between two straight lines drawn from the

Theoretical earth, the first of which is directed to the centre of the planet, and the last is a tangent to it: hence $\frac{1}{2} D = r \tan. \frac{1}{2} d$ or $r \sin. \frac{1}{2} d$, according as r is the line which touches the planet or that which is directed to its centre. Now, on account of the smallness of the angle $\frac{1}{2} d$, the sine and tangent are sensibly equal to the arc; we may therefore suppose in all cases $D = r d$. Combining this with the

equation $P = \frac{a}{r}$, we deduce $\frac{D}{a} = \frac{d}{P}$; which gives the ratio between the true diameters of the planet and the earth in terms of the apparent magnitude and horizontal parallax of the planet. It follows also from this last equation that $\frac{d}{P}$, or the ratio of the apparent diameter and parallax of a planet, is constant; the horizontal parallax may therefore be found at any time whatever by measuring the planet's diameter.

From the equation $P = \frac{a}{r}$, we have $r = \frac{a}{P}$; that is, the distance of a planet from the earth is known in terms of its parallax and the earth's semidiameter. The parallaxes, therefore, give the ratio of the distances of all the planets from the earth, and consequently of their distances from one another, and from the sun; hence the radius of the earth furnishes the scale by which the astronomer measures the dimensions of the whole solar system, and the magnitudes or volumes of all the bodies of which it is composed. On this account the accurate determination of the parallaxes of the celestial bodies is a problem of great importance in practical astronomy.

It is evident from the mere inspection of the figure, that the plane in which the straight lines CS and OS are situated is the vertical plane passing through S , consequently the whole effect of the parallax is to diminish the altitude of a planet in its vertical circle. When the observation, therefore, is made in the meridian, the effect of the parallax is to alter the declination, without producing any change whatever in the right ascension of the planet. Out of the meridian it is necessary to have regard to the azimuth or hour angle, as well as to the altitude, in calculating the correction due to the parallax. When we suppose the earth to be spherical, the formulæ for the calculation of the parallax are extremely simple, because the radius is constant, and the vertical line, or perpendicular to the surface of the earth, passes through its centre. But in the case of the true or elliptical figure of the earth neither of these circumstances takes place. The radius in this case is variable, and must be determined by a particular process of computation for every point on the meridian; and the vertical line, with reference to which the latitude of the place and the altitudes are determined, does not pass through the centre of the earth, but makes different angles with the axis. These circumstances render the calculation of the parallax a matter of much greater complication and difficulty.

The term parallax in its general signification properly denotes *change of place*. There are consequently various kinds of parallaxes, such as parallax of right ascension, of declination, longitude, latitude, &c. In what has preceded, we have supposed the earth to be at rest in the centre of the universe, and therefore have had regard solely to the variations produced in the apparent diurnal motions by the eccentric position of the observer on the surface of the earth, and which are comprehended generally under the denomination of the *diurnal* parallax.

The effects of the diurnal parallax are only sensible with regard to those bodies of which the distance from the earth is not so great as to be incomparable with the

earth's semidiameter. That the apparent place of an object must be changed in consequence of a change in the situation of the observer, is a simple geometrical truth which no experiment was required to discover. The first observers must accordingly have anticipated a parallax in all the celestial bodies; and it was doubtless only after considerable experience that they admitted the existence of any exception to the general law. There is, however, another cause of variation in the apparent positions of the celestial bodies also connected with the earth, the existence of which could not be known *a priori*, but must have been discovered by experience alone. We allude to the refraction of the rays of light in passing through the earth's atmosphere.

The angular distance between two stars is found to undergo very sensible variations at different hours of the day. This phenomenon cannot be explained by any proper motion of the stars, because it evidently depends on their altitude above the horizon; and the differences are found to be the same daily at the same altitude. It is most striking when we compare a star which, without setting, passes the meridian twice a day, once near the zenith, and the second time near the horizon, with another star situated very near the pole, and of which the altitude is consequently nearly invariable. It will be found that at the time of the first transit the distance between the two stars is greater than at the second by nearly half a degree. It is evident, therefore, that the phenomenon consists in diminishing the distance between a star situated in the horizon and the visible pole, that is to say, in elevating the stars, whereas the effect of the parallax is to depress them. The refraction also takes place in an equal degree with regard to the fixed stars, and even the moon and planets, without being in any degree modified by the great differences in the distances of the celestial bodies, contrary in this respect likewise to the parallax, which depends entirely on the distance. The reason of this will be evident from the consideration of the physical cause of the phenomenon.

According to the known principles of optics, a ray of light, in passing obliquely from one transparent medium into another of a different density, does not hold on in its rectilinear course, but is refracted, or bent towards the denser medium. Now, the atmosphere which surrounds the earth may be regarded as composed of an infinity of concentric spherical strata, the densities of which are greater in proportion as they are nearer to the earth's surface. When a ray of light, therefore, proceeding from a star enters the atmosphere, it is inflected towards the earth, or bent so as to form a smaller angle with a perpendicular to the surface of the earth; and this inflection will be increased by every successive stratum of the atmosphere through which the light passes. In fig. 8, let AA' , BB' , CC' , represent the boundaries of the successive strata, which, for the sake of illustration, we here suppose to have a finite thickness. A ray of light proceeding from S comes in contact with the highest stratum of the atmosphere AA' at a . The molecular attraction of this atmospherical stratum, acting in the direction of a normal to AA' at a , causes the luminous ray to deviate from the direction Sx , and assume another, ay , in which it would continue to move if the atmosphere were equally dense from AA' to the earth. But in the course of its progress the ray penetrates another denser stratum at b , and consequently suffers another inflection; so that instead of proceeding in the direction ay , it is bent into a new direction bz , more nearly perpendicular to the concentric strata. A similar effect is produced at c , so that the luminous ray, when it finally reaches the observer at O , has as-

Theoretical Astronomy. summed the direction cO . In its progress from a to O , it has therefore successively moved in the direction of the sides of the polygon a, b, c, O ; and to the spectator at O , the star from which it proceeded, instead of appearing in its true place at S , will appear to be at S' , or in the last direction of the visual ray. Now, if AA' is the most elevated stratum of the atmosphere into which the ray enters in the direction Sc , it is clear that the whole effect is produced by the atmospherical strata situated below AA' , and that the length of Sc is perfectly indifferent; hence the refraction is entirely independent of the distance of the stars, provided they are beyond the limits of the earth's atmosphere.

Fig. 9.

The decrease of the density of the atmosphere, from the surface of the earth upwards, follows the law of continuity, or takes place by insensible degrees; so that the luminous ray, in traversing the atmosphere, enters at every instant into a denser medium, and is therefore continually brought nearer and nearer to the vertical direction. Hence the true path of the ray is curvilinear, and concave towards the earth, as represented in fig. 9. This is equivalent to the supposition that the thickness of the different concentric strata of uniform density is infinitely small, and that the light, as it successively penetrates each, deviates from its former path by an infinitely small angle, which may be considered as the differential of the refraction, the total amount of which will therefore be obtained by integration. The direction of the ray, when it reaches the eye of the observer, is the tangent to the last portion of its curvilinear path; and the apparent zenith distance of the star will be ZOS' , while the real zenith distance is ZOS . The difference of these two angles, namely SOS , is what is denominated the *Astronomical Refraction*. It is evident that the whole path of the ray is confined to the vertical plane, in which the star and the eye of the observer are situated; for the earth and its atmosphere being very nearly spherical, that plane will divide the strata symmetrically; the attracting forces will therefore be equal on each side of it, and consequently produce no effect in a lateral direction. When the observed star is due north or south, the vertical plane is the plane of the meridian; hence, in meridional observations, the whole of the refraction, like that of the parallax, takes place in declination, while the right ascension remains unaltered.

Law of refraction.

It is evident that the amount of the refraction is greater in proportion as the observed star is nearer to the horizon; for in this case the luminous rays strike the tangent planes of the atmospherical strata more obliquely, and have besides to traverse a greater extent of atmosphere before they arrive at the eye of the observer. On determining by experiment the refraction at every altitude from zero to 90° , tables of *Refraction* may be constructed, which will furnish the means of discovering the law of its diminution; but as such a process would be exceedingly tedious, and likewise subject to lead to erroneous results on account of the inevitable errors of observation, it is found more convenient to assume some hypothesis for a basis of calculation, and to verify the results which it leads to by comparing them with observation. In regard to media which may be said to be permanent, such, for instance, as water and glass, the determination of the refraction is not attended with great difficulty; but the circumstances are greatly altered when we come to make experiments on the atmosphere. In this case the difficulty arises from the incessant changes which the atmosphere is undergoing relatively to its refringent powers; changes which it is impossible for the observer fully to appreciate, inasmuch as he can only determine its physical state within a short distance of the earth, while

that of the upper strata remains wholly unknown to him. The refringent power of the atmosphere is affected by its density and temperature. The effects of the humidity are insensible; for the most accurate experiments seem to prove that the watery vapours diminish the density of the air in the same ratio as their refractive power is greater. It is therefore only necessary, even in delicate experiments, to have regard to the state of the barometer and thermometer at the time the observation is made. At a medium density, and at the temperature of melting ice, it was found by Biot and Arago, from a great number of exact experiments, that at any altitude between 10° and the zenith the refraction is very nearly represented by the formula $r = 60'' \cdot 6 \tan. (Z - 3 \cdot 25 \times r)$, in which r is the refraction corresponding to a given zenith distance Z . With the exception of the numerical co-efficients, this formula was first given by Bradley; but whether it was deduced from theory by that great astronomer, or was only empirical, is uncertain. Bradley's formula was $r = 57'' \tan. (Z - 3 \times r)$. When the direction of the luminous rays makes a smaller angle than 10° with the horizon, it becomes indispensable to take into account, in the calculation of the refraction, the law of the variation of the density of the atmosphere at different altitudes; a law which is subject to incessant variation, from the operation of winds, and other causes which agitate the atmosphere, as well as the decrease of temperature in the superior regions. For this reason all astronomical observations which have not refraction directly for their object, or which are by their nature independent of its influence, are made at an elevation exceeding 10° . For lower altitudes, it is to be feared that no theory will ever be found sufficiently exact to entitle the observations to much confidence.

The existence of the atmospherical refraction was not unknown to the ancient astronomers; but it is only in modern times that the subject has been studied with the requisite care to admit of its influence being calculated in the reduction of observations. Ptolemy does not allude to the subject in the *Almagest*, but he has given a sufficiently exact idea of it in his work on *Optics*. He mentions experiments made to ascertain how far a ray of light is bent from its rectilinear course in passing from air into glass and water; and observes that the astronomical refraction brings a star nearer to the zenith, and that it is feebler in proportion as the star is more elevated. He likewise indicates a method of measuring its effects, although he does not seem to have attempted to practise it. The same notions, but in a less precise form, were reproduced in the *Optics* of Alhazen. Walther began to estimate the effects of refraction near the horizon; and Tycho, a century after, found the means of measuring them with greater accuracy, and was thereby enabled to construct a table. Tycho estimated the horizontal refraction at $34'$, and supposed it to vanish at the altitude of 45° ; which proves that his ideas on the subject were less accurate than those of Ptolemy, who says expressly that it vanished only at the zenith. Dominic Cassini was the first who proposed an hypothesis for calculating the refraction at any altitude; and he computed a table, which was published in 1662. Since that time the subject of refraction has been investigated, theoretically and practically, with the most scrupulous and delicate attention, and tables constructed to exhibit its amount at every altitude, and at the different seasons of the year. (See *Mécanique Céleste*, tom. iv. p. 231; Mr Ivory's Paper in the *Phil. Trans.* for 1823, p. 409; Delambre, *Astronomie du xviii. Siècle*, p. 774.)

The refringent power of the atmosphere gives rise to a number of curious phenomena. When the sun appears in

the horizon, the rays of light which issue from the extremities of his vertical diameter are refracted unequally on account of the difference of altitude, so that the disk, at other times circular, then assumes an oval appearance; and on measuring the horizontal and vertical diameters by means of the micrometer, the former is sometimes found to exceed the latter by four or five minutes of a degree. This effect is particularly remarkable when the sun is observed at his rising or setting from the top of a mountain, or an elevation near the sea-shore, in which cases the difference of the two diameters sometimes, in particular states of the atmosphere, amounts to upwards of 6', or a fifth of the whole apparent diameter of the sun. In the case of the moon this oval appearance is seldom so perceptible; for unless she happens to be exactly full, or in opposition, at the same time that she is in the horizon—and this can rarely be the case—the defect of the illumination of her disk reduces her figure to those rounder but somewhat irregular shapes which it often exhibits. The horizontal refraction being equal to the apparent diameter of the sun or moon, it happens also that either of these luminaries, and consequently any other of the celestial bodies, may be entirely visible above the plane of the horizon, when in fact it has set below it. A curious instance of this was observed at Paris in 1750. The moon rose eclipsed, while the sun, whose place at the time of a lunar eclipse is diametrically opposite to that of the moon, still appeared above the horizon. Another phenomenon occasioned by the refraction of the atmosphere is the appearance of the moon when she is eclipsed, or immersed in the earth's shadow, and consequently receives no light directly from the sun. On these occasions her disk continues distinctly visible, and is of a dusky red colour, exhibiting the appearance of tarnished copper, or iron nearly red-hot. This phenomenon occasioned great perplexity to the ancient astronomers who were unacquainted with the refractive powers of the atmosphere; and some of them ascribed it to the native light of the moon, in virtue of which she continues visible when hid from the sun's rays. Plutarch ingeniously supposed it to be occasioned by the light of the stars reflected from the dark surface of the moon; but the quantity of this light is greatly too small to produce the effect in question. It is now explained by the scattered beams of light bent into the earth's shadow by refraction in their passage through the atmosphere.

The refraction of the rays of light in traversing the earth's atmosphere is the cause of *Twilight*, which sensibly lengthens the duration of the day, and prevents a sudden transition from light to darkness on the disappearance of the sun. When the sun is more than 33' below the horizon, the refraction is not powerful enough to bring his rays sufficiently near the earth to reach our eyes; they pass over our heads, and are irregularly reflected by the molecules of the atmosphere. By this means a portion of the celestial vault is enlightened, while the sun is invisible. This illumination of the upper regions is called the twilight. It commences as soon as objects can be distinguished before sun-rise, and terminates when they cease to be visible after the sun has set. The time, however, at which the twilight commences and terminates cannot be assigned with any degree of precision. It is generally supposed to be limited by the depression of the sun 18° below the horizon. Lacaille found the limit in the torrid zone to be between 16° and 17°. According to Lemonnier, it varies in France between 17° and 21°. The duration of the twilight will evidently be longer or shorter according as the inclination of the plane of the sun's orbit to the horizon is more or less oblique.

To assign the time at which it is a maximum or minimum, or of a given length at a given latitude, is a problem of pure geometry, which has been frequently solved since the time of the Bernoullis.

The scintillation or twinkling of the stars is another phenomenon produced by certain modifications of atmospheric refraction. The atmosphere is at all times more or less agitated; and on this account the clusters of molecules of which it is composed are constantly undergoing momentary compressions and dilatations, which occasion minute differences of refraction, and consequent changes in the directions of the luminous rays. The minute and rapid variations thus occasioned in the apparent places of the stars produce the twinkling or tremulous appearances which, in certain states of the atmosphere, particularly on the approach of rain after a long drought, are very remarkable. The agitations of the atmosphere are manifest to the eye in the tremulous motion of the shadows cast from high towers, and in looking at objects through the smoke of a chimney, or over beds of hot sand. The scintillation of the planets is much less than that of the stars. This proceeds from the magnitude of their disks, which, although apparently very small, are still far greater than those of the fixed stars, and indeed so considerable, that the accidental variations in the directions of the rays of light are too minute to displace them entirely. The borders of their disks are affected only by a slight undulation; whereas the stars, which are merely brilliant points of insensible magnitude, undergo a total displacement.

The apparent enlargement of the sun and moon in the horizon is an optical illusion, connected in some measure with the atmosphere, of which various explanations have been given since the time of Ptolemy. According to the ordinary laws of vision, the celestial bodies, particularly the moon, which is nearest to the earth, ought to appear largest in the meridian, because their distance is then less than when they are near the horizon; and yet daily experience proves that the contrary takes place. To an observer placed at E (fig. 10), the visual angle subtended by the moon in the horizon at M is somewhat less than that under which she appears in the zenith at O; and this fact, a consequence indeed of her circular motion, is proved by accurate measurements of her diameters in those circumstances by the micrometer. The mean apparent diameter of the moon, at her greatest height, is 31' in round numbers, but in the horizon she seems to the eye two or three times larger. The commonly received explanation of this phenomenon was first given by Descartes, and after him by Dr Wallis, James Gregory, Malebranche, Huygens, and others, and may be stated as follows. The opinion which we form of the magnitude of a distant body does not depend exclusively on the visual angle under which it appears, but also on its distance; and we judge of the distance by a comparison with other bodies. When the moon is near the zenith there is no interposing object with which we can compare her, the matter of the atmosphere being scarcely visible. Deceived by the absence of intermediate objects, we suppose her to be very near. On the other hand, we are used to observe a large extent of land lying between us and objects near the horizon, at the extremity of which the sky begins to appear; we therefore suppose the sky, with all the objects which are visible in it, to be at a great distance. The illusion is also greatly aided by the comparative feebleness of the light of the moon in the horizon, which renders us in a manner sensible of the interposition of the atmosphere. Hence the moon, though seen under nearly the same angle, alternately appears very large and very small. Desaguliers illustrated the doctrine of the horizontal moon on the

Theoretical Astronomy. supposition of our imagining the visible heavens to be only a small portion of a spherical surface, as *mno*p (fig. 10), in which case the moon, at different altitudes, will appear to be at different distances, and therefore seem to vary in magnitude, as at *m*, *n*, *o*. It is evident, however, that this affords no explanation of the phenomenon; for why does the sky, it may be asked, appear to be a smaller segment than a hemisphere? In the solution of this question the whole difficulty is contained.

Fig. 10.

It may be remarked that these illusions disappear as soon as the intermediate objects are concealed from view. They may be destroyed by regarding the moon through a tube, which permits her disk alone to be seen, and in this manner she will appear no larger at the horizon than near the zenith. The same effect may be produced by viewing her through a smoked glass, because the dark tint permits only the luminous object to be seen, and conceals all the rest. The only precaution necessary to be observed in making this experiment, is to place the eye in such a position that the surrounding bodies may not be visible.

CHAP. II.

OF THE SUN.

SECT. I.—Of the Apparent Circular Motion of the Sun in the Ecliptic, and Position of the Ecliptic in Space.

The consideration of the diurnal motion common to all the celestial bodies, and the succession of day and night resulting from it, forms the first object of astronomy. The second is to pass from the diurnal motion of the sphere to the proper motion of the sun, and from the vicissitudes of the day to the seasons of the year. The sun, as has already been remarked, is constantly shifting his place among the stars. If we observe the altitude of any star, or group of stars, above the eastern horizon at sun-set, we shall find, on making the same observation a few days afterwards, that its elevation is considerably increased, and that it has approached nearer to the meridian. At the end of three months it will appear at sun-set on the meridian, and from that time continue to advance nearer and nearer to the sun, till it is at last concealed by the splendour of his rays. After remaining for some time invisible, it will again make its appearance in the morning to the westward of the sun, and its distance from him will continue to increase daily, till, at the end of a year, it has made a complete circuit of the sky, and regained the position it occupied at the time of the first observation. The earliest observers explained this phenomenon by supposing the diurnal motion of the sun to be less rapid than that of the stars, in consequence of which he constantly falls behind them. This supposition would be admissible if the sun remained constantly in the plane of the equator; but as he deviates considerably from that plane, on both sides of it, it is infinitely more simple to ascribe to the sun a motion of his own, independent of the diurnal motion, and performed in a contrary direction, in virtue of which he traces an oblique route among the stars.

The oblique path of the sun may be determined by observing the positions of the stars near which he successively passes in the course of the year. The same object is however accomplished with much greater precision by the modern practice of observing his declinations and right ascensions, that is to say, his distances from the equator, and an arbitrary meridian. In this manner his place may be accurately assigned every day; and, by a repetition of similar observations, a series of points will be obtained on the surface of the celestial sphere, which

mark out his annual course. The result of constant experience shows, that the declination reaches its maximum on the south side of the equator about the 22d of December, when it amounts to 23°465 degrees. From this time it gradually diminishes till about the 21st of March, when the sun reaches the plane of the equator. At this time the days and nights are of equal length all over the earth, and the instant of time at which the sun's centre is in the equatorial plane is called the instant of the equinox. The sun then appears on the opposite side of the equator, and his declination or meridional altitude continues to increase till about the 22d of June, when he becomes stationary, and then again shapes his course towards the equator. His maximum declination on the north side of the equator is exactly equal to that on the south, amounting to 23°465. The sun now continues to approach the equator till about the 24th of September, when he again reaches that plane, and a second equinox succeeds. Continuing still to move in the same direction, he declines from the equator southward, till he reaches his former limit about the 22d of December, after which he resumes his former course.

The two small circles of the sphere, parallel to the Tropics, equator, which pass through the two points where the declination is great, are called the *Solstices*, or the *Tropics*; that on the northern hemisphere is called the *Tropic of Cancer*, and the other is called the *Tropic of Capricorn*. These two parallels, which mark the extreme limits of the sun's declination, are, as has just been stated, equally distant from the equator, with regard to which the variations of declination on either side are perfectly symmetrical and uniform.

If at the time of the vernal equinox we remark the stars which set in the true west while the sun is rising in the east, and which are then separated from him by a semi-circumference, it will be found that the difference of their right ascensions, and the right ascensions of those which have precisely a similar situation relatively to the sun at the time of the autumnal equinox, is exactly 180°. It follows, therefore, that the solar orbit intersects the equator in two points diametrically opposite; but we have seen that its northern and southern declinations are equal; hence the orbit projected on the sphere must be a great circle, provided it lies wholly in the same plane. Whether this is the case or not it will be easy to prove by means of a few observations, in the following manner.

Let *AQ* (fig. 11) be the equator, *AE* the orbit of the sun, *PSM*, *PTN* two circles of declination, drawn through any two points *S* and *T* of the orbit. If the sun's path is confined to a plane, then *AE* must be a great circle, and

we shall have the equation $\sin. AM = \frac{\tan. MS}{\tan. MAS}$ according

to the well-known properties of spherical triangles. Let the cotangent of the unknown but constant angle $MAS = n$, the declinations $MS = D$, $NT = D'$, the right ascensions $AM = \mathcal{A}$, $AN = \mathcal{A}'$; then, according to the above formula, we must have $\sin. \mathcal{A} = n \tan. D$, and $\sin. \mathcal{A}' = n \tan. D'$, at whatever points of the orbit *S* and *T* may be situated. From these two last equations there result also $\cos. \mathcal{A} = \sqrt{1 - n^2 \tan^2 D}$, $\cos. \mathcal{A}' = \sqrt{1 - n^2 \tan^2 D'}$, which, being substituted in the trigonometrical formula $\sin. (\mathcal{A}' - \mathcal{A}) = \sin. \mathcal{A}' \cos. \mathcal{A} - \cos. \mathcal{A}' \sin. \mathcal{A}$, we shall have $\sin. (\mathcal{A}' - \mathcal{A}) = n \tan. D' \sqrt{1 - n^2 \tan^2 D} - n \tan. D \sqrt{1 - n^2 \tan^2 D'}$. The observations of the meridional altitudes will give the declinations *D* and *D'*; and the difference of right ascensions, $\mathcal{A}' - \mathcal{A}$, will be found by comparing the time of the sun's culmination, or transit over

Sun's
course
in the
heavens.

the meridian, with that of a star. If, therefore, it is found that, by assigning a certain constant value to n , this equation will satisfy all the observations, combined by pairs, of the sun's right ascensions and declinations, it will follow that the plane determined by any two points in the sun's course and the point in which it intersects the equator, has always the same inclination to the equator; in other words, all the planes so determined are identical.

Now the observations of the sun's right ascensions and meridional altitudes, which have been made daily during so great a number of years, and under so many different meridians, are found to conform entirely with the preceding formulæ: they therefore furnish so many proofs that the projection of the sun's orbit is a great circle of the celestial sphere, and that the orbit itself is wholly confined to the same plane.

The great circle which the sun describes in virtue of his proper motion is called the *Ecliptic*. It has received this name from the circumstance that the moon, during eclipses, is either in the same plane or very near it. These phenomena can in fact only happen when the sun, earth, and moon are nearly in the same straight line, and, consequently, when the moon is in the same plane with the earth and the sun. The angle formed by the planes of the ecliptic and equator, and which is measured by the arc of a circle of declination intercepted between the equator and tropic, is called the *Obliquity of the Ecliptic*. The two points in which the equator and ecliptic intersect each other are called the *Equinoctial Points*: they are also denominated the *Nodes of the Equator*; and the straight line conceived to join them is the *Line of the Equinoxes*, or the *Line of the Nodes*. The node through which the sun passes on coming from the south to the north of the equator is called the *Ascending Node*, and is usually distinguished by the character $\varnothing$; the opposite node is the *Descending Node*, and is marked by $\ominus$. A straight line passing through the centre of the earth, perpendicular to the plane of the ecliptic, is called the *Axis*, and the points in which its prolongation meets the sphere are called the *Poles of the Ecliptic*; these denominations being analogous to those of the axis and poles of the equator. The two small circles of the sphere which pass through the poles of the ecliptic, and are parallel to the equator, are called the *Polar Circles*.

The ecliptic has been divided by astronomers, from time immemorial, into twelve equal parts, called *Signs*, each of which consequently contains 30 degrees. The names and symbols by which they are characterized are as follows:—

North of the Equator.		South of the Equator.	
Aries.....	$\varnothing$	Libra.....	$\varnothing$
Taurus.....	$\varnothing$	Scorpio.....	$\varnothing$
Gemini.....	$\varnothing$	Sagittarius.....	$\varnothing$
Cancer.....	$\varnothing$	Capricornus.....	$\varnothing$
Leo.....	$\varnothing$	Aquarius.....	$\varnothing$
Virgo.....	$\varnothing$	Pisces.....	$\varnothing$

In each of these signs the ancients formed groups of stars, which they denominated *asterisms*, *constellations*, *animals* ($\zeta\omega\delta\iota\alpha$), not confined to the ecliptic, but included within an imaginary belt, extending 8° on each side of it, to which they gave the name of *Zodiac* ($\zeta\omega\delta\iota\alpha\kappa\omicron\varsigma\ \nu\omicron\lambda\lambda\omicron\varsigma$, *circle or zone of the animals*). The term *sign* is now employed only to denote an arc of 30°, and will probably soon be banished entirely from the astronomical tables. It is already confined to the tables of the planets. Thus, to denote that the longitude of a planet is 276° 12', it is usual to write 9° 6' 12'. Formerly it was usual to employ the characteristic symbol, and to write $\varnothing$ 6° 12', meaning that the planet was 12' in the 6th degree of Capricornus,

or the tenth sign. This inconvenient practice is now laid aside, and the signs, when they are employed, are simply distinguished by the ordinal numbers.

As the greater part of the celestial phenomena connected with the planetary system take place either in the ecliptic or in planes not greatly inclined to it, it is found to be most convenient to refer the positions of the planets, and frequently those of the stars also, to that plane. The first point of Aries, which is the technical expression for the intersection of the ecliptic and equator, or the place of the sun at the vernal equinox, is assumed as the origin from which the degrees of the equator, as well as of the ecliptic, are counted from west to east, or in the direction of the sun's annual motion. The angular distance of the sun from this point is called his *Longitude*; and the longitude of a star is the arc intercepted on the ecliptic between the same point and a great circle passing through the star perpendicular to the ecliptic. The arc of this circle intercepted between the star and the ecliptic, or, which is the same thing, the complement of the star's distance from the pole of the ecliptic, is called the *Latitude* of the star; so that longitude and latitude are with regard to the ecliptic what right ascension and declination are with regard to the equator. Thus, let O $\varnothing$ Q (fig. 12) be the equator, I $\varnothing$ L the ecliptic, P and E the north poles of these two circles respectively, and S the place of a star. Having drawn through the pole of the ecliptic and the star the great circle ESM perpendicular to the ecliptic in M; then $\varnothing$ M is the longitude of S, counted on the ecliptic from the vernal point $\varnothing$ towards the east; and SM, the distance of the star from the ecliptic, is its latitude; and for this reason all great circles passing through the poles of the ecliptic are called *Circles of Latitude*. The place of a star is thus determined by its longitude $\varnothing$ M, and its latitude SM, as well as by its right ascension $\varnothing$ R, and its declination SR; and when the angle L $\varnothing$ Q is known, it is easy to pass from the one system of co-ordinates to the other by means of the formulæ of spherical trigonometry. These formulæ are of constant use, for it is the declinations and right ascensions only which are directly observed.

The plane of the sun's orbit will be determined completely when its inclination to the equator and the position of the line of the nodes in space have been made known by observation. The declination of the sun twice a year, namely, at the summer and winter solstice, is equal to the obliquity of the ecliptic; whence, if the solstice happened exactly at mid-day, the obliquity would be given directly by an observation of his meridional altitude. This circumstance, however, can happen only for one terrestrial meridian; but as the declination of the sun when he approaches the tropics varies little from one day to another, his greatest observed declination will be a very near approximation to the obliquity, at whatever part of the earth the observation may have been made. It is easy, however, to correct the error which results from the observation being made on a meridian different from the solstitial colure. Taking an example from Woodhouse, let us suppose the sun's declination to be observed on three successive days (the 20th, 21st, and 22d of June), and found to be on these days respectively,

23° 27' 37", 23° 27' 41", 23° 27' 20";

then it is obvious, that if the middle observation gave the greatest inclination exactly, the other two would differ from it equally, which they do not. The maximum declination is therefore a quantity somewhat different from 23° 27' 41"; and it is easy to conclude, from the inspection of the numbers, that it is nearer to 23° 27' 41" than to either of the other two. It is obvious, therefore, that that observation must have been made within 12 hours of the

Theoretical Astronomy. order to form an exact notion of the amount of error which may possibly arise from this circumstance, let S Pl. LXXX. (fig. 13) be the place of the sun at the time of the observation, and X the true but as yet unknown solstitial point, and S s, X x meridional arcs intersecting the equator in s and x. The arc SX must be less than 30', for in 12 hours the variation of the sun's longitude does not exceed an arc of that magnitude. Suppose it 30': then, by Napier's rules,

rad. $\times \sin. S s = \sin. \varphi \times \sin. S \varphi$,
and rad. $\times \sin. X x = \sin. \varphi \times \sin. X \varphi$;
whence, on eliminating $\sin. \varphi$, and observing that
 $\sin. X \varphi = \sin. 90^\circ = 1$, we shall have

$$\sin. X x = \frac{\sin. S s}{\sin. S \varphi} = \frac{\sin. S s}{\cos. S X}.$$

By taking, according to the observation, $S s = 23^\circ 27' 41''$, and $S X = 30'$, we shall find from the logarithmic tables $X x = 23^\circ 27' 44''.5$. It will be observed that 30' is the maximum error in longitude; if instead of 30' it had been supposed only 3', the corresponding error in declination would have amounted only to $0''.035$. In the example chosen, the error of longitude is about 20', whence the error of declination is $1''.5$ nearly, and consequently the resulting obliquity differs little from $23^\circ 27' 42''.5$. This result is, however, to be understood of the *apparent* obliquity, which is subject to slight variations, depending on the longitudes of the moon's nodes: the *mean* obliquity,

Theoret. Astronomy. deduced from the comparison of a great number of observations, both of the summer and winter solstice, may be regarded as amounting to $23^\circ 27' 41''$ at the commencement of the year 1830. We shall see, when we come to speak of the *Nutation*, in what the difference between the apparent and mean obliquity consists.

When the mean value of the obliquity of the ecliptic, as determined by the delicate instruments of the present day, is compared with that given by ancient observations, it appears to have undergone a progressive diminution, and is always greater as the observation is more remote. The ancient observers were not, indeed, possessed of the means of determining an element of this sort with great precision; but as all the observations recorded in history agree in making the obliquity greater in former times than it is now, the probability is almost infinite that the angle formed by the planes of the equator and ecliptic has really diminished; for, had the differences of the values assigned to it arisen solely from errors of observation, they would have been in excess and defect indifferently, instead of being, as they are, uniformly in excess. The various observations and traditions by which the progressive diminution of the obliquity is confirmed have been collected by Bailly; in the following table we have inserted those which appear to be the best authenticated, and have added the results of some recent observations, which exhibit the present value of the obliquity, and the rate of its diminution.

Year.	Name of Observer.	Obliquity.	Year.	Name of Observer.	Obliquity.

Secular rate of diminution.

Although the comparison of these observations with one another gives very discordant results relatively to the law according to which the obliquity varies, their totality places the fact of its progressive diminution beyond all manner of doubt. Lacaille, who was followed by the greater number of astronomers, estimated the diminution of $44''$ in a hundred years; a result to which he was led chiefly by a comparison of his own observations with those of Walther. Lalande, after comparing an immense number of modern observations with those of the 17th, 16th, and 15th centuries, and also with those of the Arabians and Chinese, found the secular diminution to be $50''$. Bessel, rejecting the ancient observations as too uncertain, and comparing those only which have been made since the time of Bradley, has fixed the secular diminution at $45''.7$, which differs inconsiderably from the determination of Lacaille. It cannot yet be determined by observation whether this diminution is uniform, or accelerated, or retarded; but so slow is the rate at which it

proceeds, that it may, without any sensible error, be regarded as uniform for many centuries to come.

The gradual diminution of the obliquity of the ecliptic might lead us to suppose that a time will ultimately arrive when that plane will coincide with the equator, and the earth be deprived, in consequence, of the agreeable vicissitude of the seasons. But the theory of universal gravitation, which has revealed the cause of the diminution, has also shown that there are certain limits which the angle of the two planes can never exceed, and between which it must continue for ever to oscillate. Geometers have not yet ventured to assign the precise extent of these limits, but their existence is certain; and the planes of the ecliptic and equator, which have been approaching to each other during the last 2000 years, will, in the course of some thousands of years more, begin to recede.

In what has yet been said respecting the diminution of the obliquity of the ecliptic, no fact has been mentioned from which it can be inferred, whether the phenomenon is *displacement of the ecliptic*.

Theoretical Astronomy. occasioned by the displacement of the plane of the ecliptic or that of the equator. This question may also be decided by a comparison of modern with ancient observations; for it is evident, that if the inclination of these two planes becomes less, the stars which are situated between them, particularly those near the solstitial colure, will appear to approach to that plane which changes its position; so that if the ecliptic is displaced, the latitudes of those stars will be diminished, or their declinations if the displacement belongs to the equator. It was first observed by Tycho, and the observation has been confirmed by succeeding astronomers, that the latitudes of the southern stars situated near the solstitial colure, that is, of those stars whose longitudes are nearly 90° , have diminished upwards of $20'$ since the time of Hipparchus and Ptolemy, while the latitudes of the northern stars have undergone a corresponding augmentation. From this fact it is proved that the diminution of the obliquity is occasioned by the displacement of the ecliptic; and theory has shown that the cause of the displacement is the action of the planets, particularly of Jupiter and Venus, on the earth, by virtue of which the plane of the earth's orbit is drawn nearer to the planes of the orbits of these two planets. This, however, though by far the most considerable, is not the sole cause of the phenomenon; for theory also shows that a slight motion of the plane of the equator is produced by the attraction of the sun and moon, but so very minute that its effects will only become appreciable after a long series of ages.

Precession of the equinoxes. After determining the inclination of the plane of the ecliptic to that of the equator, the only element requisite to fix its position absolutely in space, is the situation of the straight line formed by its intersection with that plane, that is to say, the line of the nodes. The longitudes of the stars, as has already been mentioned, are counted on the ecliptic from the vernal equinox; and therefore, if the line of the equinoxes, which is the same as the line of the nodes, is invariable, the longitude of any star will always be the same, whatever interval of time may elapse between two observations of that longitude. But on comparing the actual state of the heavens with the observations recorded by ancient astronomers, it is perceived that the longitudes of all the stars are considerably increased; whence we must infer, either that the whole firmament has advanced in the order of the signs, or that the equinoctial points have gone backwards, or retrograded. The latter supposition is infinitely the more probable; for it is inconceivable that the innumerable multitude of stars should have a common motion relatively to points which depend solely on the motion of the earth. The phenomenon is therefore to be explained by attributing to the equinoctial points a retrograde motion from east to west, in consequence of which, the sun, whose motion is direct, arrives at them sooner than if they remained at rest; and therefore the equinoxes, spring, autumn, and the other seasons, happen before the sun has completed an entire circuit. On this account the motion has been denominated the *Precession of the Equinoxes*. As this motion is extremely slow, its exact amount can be discovered only by a comparison of observations separated from each other by long intervals of time; but the imperfection of instruments prior to the sixteenth century renders the ancient observations of little authority where quantities so minute are concerned, and therefore some discrepancies may be expected in the different determinations of the amount of the precession. The comparison of modern observations with those of Hipparchus gives its annual amount equal to $50\frac{2}{3}$ seconds, and with those of Ptolemy somewhat greater. The mean result of the observations of Tycho,

compared with those of Lacaille, gives $50''\frac{1}{3}$. On comparing modern observations with one another, we find $50''\cdot06$. Delambre, in his solar tables, supposes the annual precession to be equal to $50''\cdot1$. According to this estimate the equinoctial points go backwards at the rate of one degree in 71·6 years nearly, and therefore will make a complete revolution of the heavens in about 25,868, or nearly 26 thousand years.

The discovery of the precession of the equinoxes is generally attributed to Hipparchus, who, on comparing his own observations with those of Timocharis, more ancient by 160 years, perceived that in this interval the longitudes of the stars had been augmented by about two degrees. It would seem, however, from many proofs collected by Bailly, that this motion, slow as it is, was known to all the ancient nations who cultivated astronomy, long before the time of Hipparchus. It is indeed easy to conceive, from the great attention which they gave to the heliacal risings of the remarkable stars, that they might observe a gradual change of the seasons at the occurrence of these phenomena, from which they would necessarily be led to conclude a variation of the star's longitude. In consequence of this regression of the equinoctial points, the sun's place among the zodiacal constellations at any given season of the year is now greatly different from what it was in remote ages. Some time prior to Hipparchus, the first points of Aries and Libra corresponded to the vernal and autumnal equinoxes; those of Cancer and Capricorn to the summer and winter solstices: at present these constellations have receded 30 degrees from the same points of the ecliptic. The vernal equinox now happens in the constellation Pisces, the summer solstice in Gemini, the autumnal equinox in Virgo, and the winter solstice in Sagittarius. Astronomers, however, still count the signs from the vernal equinox, which, therefore, always corresponds to the first point of the *Sign of Aries*. On this account it is necessary to distinguish carefully between the *Signs* of the Zodiac, which are fixed with regard to the equinoxes, and the *Constellations*, which are movable with respect to those points.

The diminution of the obliquity of the ecliptic arises from the displacement of the ecliptic itself; the precession of the equinoxes is, on the contrary, occasioned by the continual displacement of the plane of the terrestrial equator. This displacement results from the combined action of the sun and moon (for the influence of the planets amounts only to a fraction of a second, and is consequently scarcely sensible,) on the mass of protuberant matter accumulated about the earth's equator, or the matter which forms the excess of the terrestrial spheroid above its inscribed sphere. The attracting force of the sun and moon on this shell of matter may be resolved into two; one parallel to the plane of the equator, the other perpendicular to it. The tendency of this last force is to diminish the angle which the plane of the equator makes with that of the ecliptic; and if the earth had no motion of rotation, it would soon cause the two planes to coincide. In consequence, however, of the rotatory motion of the earth, the inclination of the two planes remains constant; but the effect produced by the action of the force in question is, that the plane of the equator is constantly shifting its place, in such a manner that the line of the equinoxes advances in the direction of the diurnal motion, or contrary to the order of the signs, its pole having a slow angular motion about the pole of the ecliptic, so slow indeed, that it requires nearly 26,000 years to complete its revolution.

If the sun and moon moved in the plane of the equator, there would evidently be no precession; and the effect of Nutation.

Physical cause of the precession of the equinoxes.

Theoretical
Astronomy.

their action in producing it varies with their distance from that plane. Twice a year, therefore, the effect of the sun in causing precession is nothing; and twice a year, namely at the solstices, it is a maximum: on no two successive days of the year is it exactly the same, and consequently the regression of the equinoctial points, which results from the sun's action, must be unequal. On this account the obliquity of the ecliptic is subject to a semi-annual variation; for the sun's force, which tends to produce a change in the obliquity, is variable, while the diurnal motion of the earth, which prevents the change from taking place, is constant. Hence the plane of the equator is subject to an irregular motion, which is technically called the *Solar Nutation*. The existence of the solar nutation is, however, only a deduction from theory, for its amount is too small to be perceptible to observation; but a similar effect of the moon's action is sufficiently appreciable, and was, in fact, discovered by Dr Bradley before theory had indicated its existence. Its period, however, is different, and depends on the time of the revolution of the moon's nodes, which is performed in 18 years and about 7 months. During this time the intersection of the lunar orbit with the ecliptic has receded through a complete circumference; and the inequality of the moon's action will consequently, in the same time, have passed through all its different degrees. Bradley observed that the declinations of the stars continued to augment during nine years, that they diminished during the nine years following, and that the greatest change of declination amounted to 18". He remarked further, that this motion was connected with an irregularity of the precession of the equinoxes, which followed exactly the same period; whence he concluded that the motion of the poles of the equator, occasioned by this vibration of its plane, was not confined to the solstitial colure. A series of observations on stars differently situated proved that all the phenomena could be explained on the hypothesis that the pole of the equator describes in 18 years a small circle of 18" diameter, contrary to the order of the signs; or that the axis of the world, following the circumference of this circle, describes the surface of a cone, the axis of which forms with its side an angle of 9". This apparent vibratory motion is significantly denominated the *Nutation of the Earth's Axis*.

Path described in space by the pole of the equator.
Fig. 14.

In consequence of the two motions which occasion the precession and the nutation, the true path of the pole of the equator round that of the ecliptic is an epicycloidal curve, which will be understood by referring to fig. 14. Let E be the pole of the ecliptic, round which the pole of the equator P describes, in virtue of the precession, and in a direction contrary to the order of the sines, the circle PQR, of which the radius EP is equal to the obliquity of the ecliptic, or the mean distance of the two poles. While P, the mean place of the pole, moves in the circle PQR, with a velocity equal to the regression of the equinoctial points, or at the rate of $50''.1$ a year, the true pole p describes at the same time round P a small circle of 18" diameter in the same direction pqr . The true path of the pole is therefore along the circumference of a circle pqr , the centre of which retrogrades on the circumference of another circle, and consequently moves in an epicycloid $abcdefg$, the curve which results from the composition of the two motions. Suppose the mean pole at Q, the true pole at a , and $aQ = 9''$. In the course of nine years the mean pole will have retrograded from Q to R, making $QR = 9 \times 50''.1$, while the true pole will have accomplished a semi-revolution in its circle. It will therefore be at c (Rc being $= 9''$), and have described the epicycloidal arc abc , the greatest distance of which from the circle PQR is at b , and equal to $9''$. At the end of the following

nine years the mean pole has retrograded from R to S, or $9 \times 50''.1$, and the true pole has returned to the same point a of its epicycle; it will therefore be found at e , Se being $= 9''$. In this interval it has necessarily been within the circle PQR, its greatest distance from which at d is $9''$, so that in 18 years it has traced the curve $abcde$. But $ac = QR + aQ + Rc = 9 \times 50''.1 + 18'' = 7' 49''$, and $ce = RS - Rc - Se = 9 \times 50''.1 - 18'' = 7' 13''$. From a to c the motion of the true pole in the epicycle is in the same direction as that of the mean pole; from c to e it is in an opposite direction, but as it is always much slower, being only about $3''$ in a year, while that of the mean motion is $50''.1$, the true motion which results from the combination of both will always be in the direction ce , and at d its velocity will be equal to their difference. At b and d the difference between the latitudes of the true and mean pole is a maximum, while the difference of their longitudes is nothing; in other words, the correction of the obliquity is greatest when that of the precession vanishes: at a , c , and e the correction of the obliquity vanishes, and that of the precession is a maximum.

Dr Bradley remarked that the effects of the nutation would be represented still more accurately by supposing the curve described by the pole of the equator about its mean place to be an ellipse instead of a circle, the transverse and conjugate axes being $18''$ and $16''$ respectively. This is also confirmed by theory, from which Laplace calculated the semi-axes of the ellipse at $9''.63$ and $7''.17$. The semi-transverse axis of the ellipse described by the pole in virtue of the sun's action alone does not exceed half a second, and is consequently totally inappreciable. The sensible part of the nutation, therefore, follows exactly the period of the revolution of the nodes of the moon. From a series of 810 observations, embracing three complete revolutions of the moon's node, the major and minor semi-axes of the ellipse have been found by M. Lindenau to be $8''.977$ and $6''.682$ respectively.

It is now easy to see the reason of the distinction drawn above between the *mean* and the *true* or *apparent* obliquity. The mean obliquity is represented by the radius EP of the deferent circle PQR, along the circumference of which the centre of the small circle or ellipse is carried, while the true obliquity is that quantity increased or diminished by the nutation. The calculation of the mean obliquity from the true is performed by the aid of the astronomical tables.

The progressive diminution of the mean obliquity and the nutation of the earth's axis are inequalities distinguished from each other, not only by their being derived from different and distinct causes, but still more by the very great difference of time required for their full development. Almost every other element of the planetary system is affected in a similar manner by inequalities of two kinds, which are distinguished by the terms *secular* and *periodic*. The secular inequalities proceed with extreme slowness, and continue progressive in the same sense during many centuries; while the periodic are much more rapid in their march, and run through the whole period of their changes in comparatively short intervals of time. The inequalities of the first kind are also periodic; but their periods are vastly longer, and may be reckoned by centuries instead of years; and from this circumstance they derive their name of *secular inequalities*.

SECT. II.—Of the Orbit of the Sun.

Having now considered the situation of the plane in which the sun is observed to move relatively to the fixed stars, and also the small secular and periodic variations

Pole describes ellipse.

Theoretical to which it is subject, we proceed next to inquire into the nature of his orbit, or the curve which he describes on that plane. The means which we have of determining the solar orbit are the observed variations of the sun's angular velocity, and of his distance from the earth; hence two kinds of observations are necessary,—the first, of his daily meridional altitudes, from which, as the inclination of the orbit is known, his angular velocity is easily found; and the second, of his apparent diameter, the variations of which follow the inverse ratio of his distance.

That the angular velocity of the sun's motion in his orbit is not uniform, is obvious from the fact that he remains $7\frac{2}{3}$ days longer in the northern than in the southern signs, or, which is the same thing, that the interval between the vernal and autumnal equinoxes is $7\frac{2}{3}$ days longer than the interval between the autumnal and vernal. It is proved by numerous observations that the sun moves with the greatest velocity when at a point situated near the winter solstice; while at the opposite point of the orbit, or near the summer solstice, his velocity is the least. At the first point the diurnal motion is $1^{\circ}01'943$, and at the second only $0^{\circ}95'319$. It is constantly varying between these two points; and the variation is observed to be nearly proportional to the sun's angular distance from the point of his orbit where his velocity is a maximum or minimum. The mean velocity is $0^{\circ}98'632$, or nearly $59' 11''$, which is the rate of the sun's daily motion about the beginning of April and October.

The point of the solar orbit, which is the most remote from the earth, is called the *apogee* ($\alpha\pi\omicron\gamma\eta\varsigma$, away from the earth); that which is nearest is called the *perigee* ($\pi\epsilon\rho\gamma\eta\varsigma$, near the earth). The same points are also called respectively the superior and inferior *Apsis* of the orbit, and the straight line which joins them is called the *Line of the Apsides*.

The exact determination of the sun's diameter is a problem which engaged the earliest astronomers, but of which, before the invention of the telescope and micrometer, it was impossible to obtain a solution sufficiently accurate to make known its variations. Archimedes, by an extremely ingenious though imperfect method, demonstrated that it must be included between the limits $\frac{1}{800}$ and $\frac{1}{160}$ of a right angle, that is, between $27'$ and $32' 55''7$. The Egyptians, by observing the time which the sun takes to rise above the horizon, found it to be between a 750th and a 700th part of a circumference, that is, between $28' 48''$ and $30' 51''5$. Aristarchus of Samos supposed it to be $30'$. The precision of modern observations shows that the apparent diameter is greatest about the time of the winter solstice, and least about the summer solstice; but there is some discrepancy among the results of different astronomers with respect to its actual magnitude. According to Lalande, the greatest apparent diameter, about the end of December, is $32' 35''5$; the least, about the end of June, $31' 30''5$. According to the tables of Delambre, its greatest value is $32' 35''6$, and its least $31' 31''$; the mean apparent diameter, or the diameter at the sun's mean distance, is equal to $32' 2''9$.

From these remarks it is obvious, that if the orbit of the sun be a circle, the earth is not situated in the centre of that circle, otherwise the distance of the sun from the earth would remain always the same, which is contrary to fact. It is possible, however, that the variation in his angular velocity may not be *real*, but only *apparent*. Thus, in fig. 15, let AMPN be the orbit of the sun, C the centre of that orbit, and E the position of the earth at some distance from the centre. It is obvious that P is the sun's perigee, and A his apogee. Now, as the sun's apparent orbit is a circle having the earth in its centre, it is evident that this

Theoretical Astronomy. orbit must be aMpN, and that the angular motion of the sun will be measured upon that circle. Suppose now that the sun in his apogee moves from A to A', it is obvious that his apparent or angular motion will be the segment a a' of the apparent orbit, considerably smaller than AA'; so that at the apogee the angular motion of the sun will be less than his real motion. Again, let the sun in his perigee move from P to P', describing a segment precisely equal to the segment AA'. This segment, as seen from the earth, will be referred to pp', which in that case will be the sun's angular motion, evidently considerably greater than his real motion.

Hence it is obvious, that even on the supposition that the sun moved equably in his orbit, his angular motion as seen from the earth would still vary, that is, would be smallest at the apogee and greatest at the perigee, and that the angular and real motion would only coincide in the points M and N, where the real and apparent orbits intersect each other. From the figure, it is obvious also that the angular velocity would increase gradually from the apogee to the perigee, and diminish gradually from the perigee to the apogee, which likewise corresponds with observation.

But if the variation in the angular motion of the sun were owing alone to the eccentric position of the earth within the solar orbit, it is easy to demonstrate that in that case the diminution of his angular velocity would follow the same ratio as the diminution of his diameter. The fact however is, that the angular velocity diminishes in a ratio twice as great as the diameter of the sun does. The variation of the angular velocity cannot then be owing to the eccentricity alone. Hence it follows that the variation of the motion of the sun is not merely apparent, but real, and that its velocity in its orbit actually diminishes as his distance from the earth increases. Two causes, then, combine to produce the variation in the sun's angular velocity; namely, 1. the increase and diminution of his distance from the earth, and, 2. the real increase and diminution of his velocity in proportion to this variation of distance. These two causes combine in such a manner that the daily angular motion of the sun diminishes as the square of his distance increases, so that the product of the angular velocity multiplied into the square of the distance is a constant quantity.

The observation, that the sun's angular motion in his orbit is inversely proportional to the square of his distance from the earth, is due to Kepler. The discovery was made by a careful comparison of the sun's diurnal motion with his apparent diameter, which is inversely proportional to his distance from the earth. Let ASB (fig. 16) be the sun's orbit, E the earth, and S' the sun. Suppose a line ES joining the centres of the earth and sun to move round along with the sun. It is obvious that when S moves to S', ES, moving along with it, is now in the situation ES', having described the small sector SES'. In the same time that S performs one revolution in its orbit, the radius vector ES will describe the whole area ABS inclosed within the sun's orbit. Let SS' be the sun's angular motion during one day. It is evident that the small sector SES' is proportional to the square of ES, multiplied by SS'; for the radius vector is the sun's distance from the earth, and SS' his angular motion. Hence this sector is a constant quantity, whatever the angular motion of the sun be; and the whole area SEA increases as the number of days which the sun takes in moving from S to A. Hence results that remarkable law, first pointed out by Kepler, that the areas described by the radius vector are proportional to the times of description. Suppose the sun to describe SS' in one day, and SA in twenty days; then

Theoretical Astronomy. SEA is 20 times greater than the area SES'.

Fig. 17.

The knowledge of these facts enables us to draw upon paper, from day to day, lines proportional to the length of the radius vector of the solar orbit, and having the same relative position. If we join the extremity of these lines, by making a curve pass through them, we shall perceive that this curve is not exactly circular. Let E (fig. 17) represent the earth, and E a, E b, E c, E d, E e, &c. the position and length of the radius vector during every day of the year; if we join together the points a, b, c, d, e, f, g, h, i, k, l, m, n, o, by drawing the curve *a e i m* through them, it is obvious that this curve is not a circle, but elongated towards *a* and *i*, the points which represent the sun's greatest and least distance from the earth. The resemblance of this curve to the ellipse induced Kepler to compare them together; and he ascertained their identity, and thus proved that the orbit of the sun is an *ellipse*, having the earth in one of its foci.

Having arrived at the knowledge of the true nature of the sun's orbit, it becomes necessary, in the next place, to determine its position on the plane of the ecliptic, that is, to assign the position of the transverse axis, or line of the apsides, with reference to some other straight line given by position on that plane. The line which it is most convenient to assume for this purpose is the line of the equinoxes; and the position of the apsides may be determined from observations of the time which the sun occupies in performing a semi-revolution, counting from different points of his orbit. Thus, if among the observations of the sun's longitude made daily during the course of a year, we compare, two and two, all those which are diametrically opposite, or which differ by 180° , it will be found that the interval between them will be somewhat less than half a year, if the sun, during that interval, has passed through his perigee, or longer if he has passed through his apogee; and that the time between the two observations will differ less from half the time of a whole revolution, in proportion as the sun's place, at the time of the two observations, was nearer to the apsides. If the difference of time between the two observations is exactly half a year, then the place of the apsides would be obtained at once, because the sun must have been in those points when the observations were made. The probability is, however, infinitely small, that this can ever happen exactly; but as the position of the apsides is known very nearly from the diurnal observations of the variation of the sun's angular velocity, the necessary corrections can easily be supplied by computation.

From the comparison of observations made in different ages, it appears that the position of the apsides is not fixed on the plane of the ecliptic, but that the greater axis of the solar ellipse revolves in the direction of the sun's annual motion. The observations of Hipparchus, compared with those of the present times, show that the apsides have a direct motion at the rate of $65''$ in a year. According to the observations of Walther, the longitude of the apogee in 1496 was $93^\circ 57' 57''$; and according to Lacaille, the same element in 1750 was $98^\circ 37' 28''$; whence, dividing the difference by 254, the interval between the two epochs, the annual motion of the line of the apsides amounts to $66''$. Delambre found, by the comparison of a great number of modern observations, that the annual motion is $61''.95$ a year. The theory of attraction, which, in respect of such slow and minute variations, must be considered as giving more accurate results than can be obtained directly by observation, gives $61''.9$ for the yearly progressive motion of the apsides.

In the above determination, the position of the ap-

sides is referred to the line of the equinoxes, and their motion compared with the sun's tropical revolution. But if we wish to determine their motion with reference to the fixed stars, it is necessary to have regard to the retrograde movement of the equinoctial points; for it is obvious, that if the line of the equinoxes is not fixed, the displacement of the apsides with respect to the stars will be increased or diminished by the whole amount of its motion, according as the two motions are in the same or opposite directions. Now the motion of the line of the apsides is direct, and has just been stated to amount to $61''.9$ in a solar year; that of the equinoxes is, on the contrary, retrograde, and amounts to $50''.1$ in the same time. Hence the displacement of the apsides, with reference to a star or fixed point in the ecliptic, is $61''.9 - 50''.1 = 11''.8$ a year, in the direction of the sun's annual motion. The time, therefore, in which the solar perigee completes a revolution in the

heavens, or returns to the same star, is $\frac{360^\circ}{11''.8}$, equal nearly to 110,000 years.

Since the greater axis of the solar ellipse has a progressive motion on the plane of the ecliptic, it forms a variable angle with the line of the equinoxes, and at distant epochs will coincide with that line, or be perpendicular to it. The epochs at which these phenomena happen may be easily found by simple proportions, when the longitude of the perigee at any given time, and its annual motion, are known. According to the observations of Lacaille, already quoted, the longitude of the perigee in 1750 was $278^\circ 37' 28''$; but when the longitude of the perigee was 270° , the greater axis of the solar ellipse must have been perpendicular to the line of the equinoxes. The difference of these two longitudes is $8^\circ 37' 28''$, and the number of years requisite to describe that arc, at the rate of $61''.9$

annually, is $\frac{8^\circ 37' 28''}{61''.9} = 500$ years nearly; whence the major axis was perpendicular to the line of the equinoxes in the year 1250, when the perigee of the orbit coincided with the winter solstice.

Suppose it were required to assign the epoch at which the major axis coincided with the line of the equinoxes. At the occurrence of this phenomenon the longitude of the perigee was 180° , consequently from that time to 1750 the perigee had advanced $278^\circ 37' 28'' - 180^\circ = 98^\circ 37' 28''$.

Now $\frac{98^\circ 37' 28''}{61''.9} = 5735$; therefore 5735 is the number of years intervening between the occurrence of the phenomenon and 1750. Hence about 4000 years before the commencement of our era, the transverse axis of the solar orbit coincided with the line of the equinoxes; and it is a singular coincidence that this epoch is considered by chronologists to be that of the beginning of the world, or, to speak more correctly, of the first traces of the existence of the human race; for numerous physical circumstances attest that the earth itself has existed during an infinitely longer period. The same phenomenon will again occur when the longitude of the perigee shall have reached 360° , or become zero; and by calculating as above, this will be found to take place in the year 6485 of our era. The solar perigee will then coincide with the vernal equinox; in the former case it coincided with that of autumn.

By reason of the progressive motion of the perigee, the length of the seasons is continually varying. Let AP (figs. 18, 19, 20) represent the line of the apsides, S and V the summer and winter solstices, V and O the vernal and autumnal equinoxes. When the greater axis was perpendicular to the line of the equinoxes, as happened in the year 1250 of our era, the perigee P (fig. 18) coincided

Theoretical with W the winter solstice; and on that account the time between the autumnal equinox O, and the winter solstice W, was equal to the time between W and V, or between the winter solstice and the vernal equinox. But in this position the equator, which is here represented by VO, divides the ellipse into two unequal portions, the smaller of which must be described in less time than the greater, because the times of description are proportional to the spaces passed over. The summer was therefore, at that time, longer than the winter, and both were divided into equal parts by the solstices. In any other position the seasons differ in length from each other. In the time of Hipparchus, the longitude of the perigee was less than in 1750 by $32^{\circ}292$, or was $246^{\circ}330$. The position of the ellipse with regard to the equinoxes was therefore such as is represented in fig. 19, the angle PEW being $270^{\circ} - 246^{\circ}33 = 23^{\circ}40'12''$. The interval between V and S was then $94\frac{1}{2}$ days, and that between S and O only $92\frac{1}{2}$ days. The spring was therefore at that time longer than the summer, and the winter longer than the autumn. The position of the ellipse in 1800 is represented in fig. 20. The angle PEW was then $9^{\circ}29'$, and the following were nearly the lengths of the seasons:—

	Days.	Hours.	Min.
from V to S.....	92	21	45
S to O.....	93	13	35
O to W.....	89	16	47
W to V.....	89	1	42

length of the year, nearly.....365 5 49

The spring is therefore at present shorter than the summer, and the autumn longer than the winter.

After describing the position of the transverse axis of the solar ellipse on the plane of the ecliptic, we come next to consider the species of that ellipse, or its eccentricity, on which depend the apparent inequalities of the sun's angular motion. It is evident that this element will be made known if we can by any means determine the ratio of the two segments into which the major axis is divided by the focus. This ratio might seem to be obtainable without any difficulty by comparing the sun's apparent diameters at the perigee and apogee, to which the distances are inversely proportional; but such observations, on account of the irradiation and other difficulties, are liable to considerable uncertainty: it is therefore necessary to have recourse to other methods of estimating the eccentricity, and the variations to which it is subject. These methods are derived from the fundamental law of the elliptic motion, namely, the proportionality of the areas described by the radius vector to the times of description, by which the inequalities of motion and the ellipticity of the orbit are connected with each other; so that when the inequalities are made known by direct observation, the species of the ellipse can be computed from the principles of geometry. It will, however, be necessary to attend more closely than we have yet done to the phenomena resulting from the eccentric position of the earth in the sun's orbit, and to explain some terms technically employed by astronomers to abbreviate and simplify their descriptions.

The sun's motion may be regarded as composed of two distinct parts, namely, a circular uniform motion, which constitutes the principal part of it; and a correction depending on the deviation of the orbit from a circle, which modifies the first, and alternately accelerates and retards the mean angular velocity. To illustrate this, let E (fig. 21) be the earth, PSA the orbit of the sun, AP the line of the apsides, and φ the intersection of the plane of the orbit with that of the equator. While the true sun

S moves round his elliptic orbit, describing areas proportional to the times, conceive a fictitious sun s to move round the earth in the circumference of a circle of which the radius is equal to EP the sun's distance at the perigee, and with a uniform motion such, that if the two suns set out at the same instant from P, they may also return to the same point together, after having completed each a revolution. At the perigee the radius vector of the real sun is a minimum; his velocity is consequently a maximum, and he therefore advances before the fictitious sun. But his motion relaxes in proportion as his distance from P becomes greater; and at a certain point S of the orbit it becomes equal to that of the fictitious sun, which has then only reached the point s . After passing the point S, the angular distance SEs continues to diminish on account that the motion of the real sun continues to relax, and it vanishes altogether when he reaches his apogee at A, the fictitious sun arriving at a in the same straight line with A and E at the same instant of time. From the apogee to the perigee the phenomena are reversed. The motion of the real sun being then the slowest possible, he at first falls behind the fictitious sun; but his motion continuing to be gradually accelerated, he has again acquired the same velocity when he reaches S', after which his motion is more rapid than that of the fictitious sun, which he at last overtakes at P. If, therefore, we conceive a radius vector to be drawn from the earth to each of the two suns, those lines will form with each other a variable angle, having its maximum value when the velocities are equal, and vanishing at the perigee and apogee. This angle, namely, SEs, is called the *Equation of the Centre*, or *Equation of the Orbit*. It is the correction necessary to be made to the longitude of the sun deduced from his equable motion, in order to have his real longitude. Those quantities which form the difference between the true and mean results are, in astronomy, denominated equations. The ancients employed the term *Prosthaphæresis* in the same sense.

From the perigee to the apogee, the true longitude of the sun is found by adding the equation of the centre to the mean longitude, and in the other half of the orbit by taking the difference of the same quantities. The equation of the centre is a maximum when the sun is at the points S and S', or when the mean and true motions are equal; and if its value can be obtained from observation at those times, the eccentricity of the orbit may be deduced by means of the geometrical properties of the ellipse. Now the points S and S' may be found very nearly by observing when the diurnal velocity of the sun is equal to the mean motion, or to 0.985647 parts of a degree. By these observations the angle SES', which is the difference of the real longitudes of the sun, or of his distances from φ , will be given. But $sE s'$ is also given; for it is the angle which would be described by the sun, in virtue of his mean motion, during the interval between the two observations. Hence the difference between sEs' and SES' is given, being equal to twice SEs the maximum equation of the centre, in consequence of the symmetrical position of the points S and S', and also of s and s' , in respect of the line of the apsides AP. The accuracy of a result obtained in this manner may appear questionable, on account of the impossibility of determining by observation the exact moment at which the sun's true motion in longitude is equal to his mean motion; but as the real motion varies very little during a few days before and after that epoch, the equation of the centre will be scarcely affected by a slight error in the time. Besides, any error in the result is corrected by taking the mean of a great number of similar observations.

Theoretical
Astronomy.

By a comparison of numerous observations of this kind, Delambre found that the greatest equation of the centre, in the year 1776, amounted to $1^{\circ} 9' 25.4''$, or $1^{\circ} 55' 31''.4$. In 1801 the same equation was $1^{\circ} 55' 27''.3$. (See *Baily's Astronomical Tables*, p. 66.)

Having obtained the value of the greatest equation of the centre, the eccentricity of the orbit may be computed from the first two terms of the following series,

$$e = \frac{1}{2}E - \frac{11}{243}E^3 - \frac{587}{216 \cdot 3 \cdot 5}E^5 - \&c.$$

in which e represents the eccentricity, and E the greatest equation of the centre. By reversing the series the following expression is found for the greatest equation in terms of the eccentricity, viz.

$$E = 2e + \frac{11}{243}e^3 + \frac{599}{216 \cdot 5}e^5 + \&c.$$

For an investigation of the above formulæ the reader may consult Biot, *Astronomie Physique*, tom. ii. p. 185.

Secular
diminu-
tion of the
eccentric-
ity of the
solar orbit.

It has been discovered by observation, that the equation of the centre of the sun's orbit is subject to a nearly uniform secular diminution. This fact is confirmed by theory, from which also the secular diminution has been assigned. It amounts to $8^{\circ} 0047'$ in a century. This phenomenon implies a corresponding diminution of the eccentricity of the solar orbit amounting to $\cdot 000037495$ in the same time, the semiaxis major being unit. This will be conceived more distinctly by converting the above fraction into some familiar expression of linear magnitude. Supposing the mean distance of the sun to be 96,000,000 of miles, the fraction $\cdot 000037495$ will represent nearly 3700 miles, so that the annual diminution of the eccentricity is nearly at the rate of 37 miles,—a line which is considerable on the surface of the earth, but which has scarcely an appreciable ratio to the immense distance of the sun. If, however, this diminution, small as it is, were to be continued indefinitely, the eccentricity would ultimately vanish, and the sun's orbit would be changed into a circle; but the theory of universal gravitation proves that, like all the other variations of the elements of the solar system, the variation of the eccentricity is subject to periodic laws. After having continued during a certain time to diminish, the eccentricity will again begin to increase, and will successively pass through all its former values. Thus it will continue to oscillate within certain limits, of which the extent, though not precisely known, cannot be very great; and the solar orbit will eternally preserve its elliptic form, unless the application of some external force shall derange the system of the world, or modify the laws by which it is at present governed.

Determina-
tion of the
sun's
place in his
orbit.

Kepler's
problem.

The true nature of the solar orbit being known, together with its situation on the plane of the ecliptic, and the amount of its eccentricity, as also the time of a revolution, the sun's longitude may be determined at any assigned epoch. This determination is what is usually termed *Kepler's Problem*, having been first proposed by that great astronomer on the hypothesis of an elliptic orbit. Its solution, which is not susceptible of being exhibited under a finite form, is derived from the principle of the equable description of areas. Let ASP (fig. 22) represent the semi-orbit of the sun, C the centre of the orbit, E the focus occupied by the earth, and let the time and motion be counted from the perigee P. On AP describe a semicircle, on the circumference of which let a point M be supposed to move uniformly, and to describe the semicircle PMA, in the same time in which the sun describes the semi-ellipse PSA. Now, suppose that at the end of a given time t , the sun has moved from P to S; then, denoting by T the time of a complete revolu-

tion, and putting π for the semi-circumference, the place of M, at the end of the same time t , will be given by the equation $PM = \frac{t}{T} 2\pi$. Through S let a perpendicular

Theoretical
Astronomy.
Fig. 2

be drawn to AP, meeting the semicircle in D and AP in N, and join EM, ES, ED, CM, and CD. The different angles of this figure have received certain technical names, which it is necessary to explain. The angle PES, which is the true longitude of the sun, is called the *True Anomaly*; PEM is called the *Mean Anomaly*, and PCD is denominated the *Eccentric Anomaly*. This last is measured by the arc PMD, which is the perigean distance of a star describing a circle circumscribed about the solar ellipse, and having constantly the same absciss PN as the sun. The word *anomaly* originally signified *inequality*; it now simply designates the angular distance of a planet from its perihelion, seen from the sun, or, as in the present case, the angular distance of the sun from his perigee.

According to the law of the equable description of areas, we have the sector PCM to PES as the surface of the semicircle to the surface of the semi-ellipse; that is, as the semi-transverse to the semi-conjugate axis, or as ND to NS, according to a well-known property of the ellipse. Hence PCM : PES :: PED : PES, and therefore PCM = PED = PCD = ECD. Now, if we express the arc PM by z , PD by x , the eccentricity EC by e , and make the radius equal to unity, we shall have the sector PCM = $\frac{1}{2}z$, the sector PCD = $\frac{1}{2}x$, and the triangle ECD = $\frac{1}{2}e$. DN = $\frac{1}{2}e \sin x$. Substituting, therefore, these expressions in the above equation, it will become, on multiplying both sides of it by 2,

$$Z = x - e \sin x \dots \dots \dots (1.)$$

where z denotes the mean, and x the eccentric, anomaly.

If in this equation x and e were both known, it would be easy to deduce from it the mean anomaly z ; but the data are z and e , and the value of x can only be obtained in a series, the equation being a transcendental one. Its resolution gives the value of the eccentric in the mean terms of anomaly; and if another equation can be found in which the eccentric anomaly is expressed in terms of the true, it will only remain to put these two expressions equal to one another in order to have an equation between the mean and true anomaly.

For this purpose it will be necessary to equate two values of the radius vector ES, expressed in terms of the eccentric and true anomalies respectively. Putting ES = r , we shall have, in the first place,

$$r^2 = EN^2 + NS^2;$$

but if the semiaxis minor is represented by b , the common equation of the ellipse gives

$$NS^2 = \frac{b^2}{a^2} (a^2 - CN^2) = b^2 - \frac{b^2}{a^2} CN^2;$$

and we have also

$$EN^2 = EC^2 + 2 EC \cdot CN + CN^2 \\ = e^2 + 2e \cdot CN + CN^2;$$

therefore, by addition,

$$NS^2 + EN^2 = b^2 + e^2 + 2e \cdot CN + \left(1 - \frac{b^2}{a^2}\right) CN^2.$$

Now, $b^2 + e^2 = a^2$, and $1 - \frac{b^2}{a^2} = \frac{e^2}{a^2}$; therefore

$$NS^2 + EN^2 = r^2 = a^2 + 2e \cdot CN + \frac{e^2}{a^2} CN^2;$$

consequently

$$r = a + \frac{e}{a} CN.$$

But CN = $a \cos x$; therefore ultimately

$$r = a + e \cos x \dots \dots \dots (2.)$$

Theoretical Astronomy. To obtain a second value of r , let SF be drawn from S to the other focus of the ellipse, and let SF = r' . The rectangular triangles ESN, FSN give $SN^2 = r^2 - EN^2$, and $SN^2 = r'^2 - (2e - EN)^2$; therefore $r^2 - EN^2 = r'^2 - (2e - EN)^2$, whence we derive $r^2 - r'^2 = 4e \cdot EN - 4e^2$. But by the property of the ellipse $r + r' = 2a$, from which it is easy to deduce $r^2 - r'^2 = 4a^2 - 4ar' = 4ar - 4a^2$; and hence, by equating these two values of $r^2 - r'^2$, $e \cdot EN - e^2 = ar - a^2$. Now, if we denote the angle PES, which is the true anomaly, by v , then $EN = r \cos. v$, and consequently by substitution, $er \cos. v - e^2 = ar - a^2$, whence

$$r = \frac{a^2 - e^2}{a - e \cos. v} \dots \dots \dots (3.)$$

If we now compare the two values of r given by the equations (2) and (3), we shall find

$$\cos. x = \frac{a \cos. v - e}{a - e \cos. v},$$

and therefore, $1 - \cos. x = (a + e) (1 - \cos. v)$
 $1 + \cos. x = (a - e) (1 + \cos. v);$

whence, by dividing,

$$\frac{1 - \cos. v}{1 + \cos. v} = \frac{a - e}{a + e} \cdot \frac{1 - \cos. x}{1 + \cos. x};$$

consequently, by the trigonometrical formulæ,

$$\tan. \frac{1}{2}v = \left(\frac{a - e}{a + e} \right)^{\frac{1}{2}} \cdot \tan. \frac{1}{2}x \dots \dots \dots (4.)$$

The equations (1) and (2) were first given by Kepler; the last is due to Lacaille. The problem of finding the sun's place after any given time is solved analytically by (1) and (4).

To express v the true anomaly, in a series involving the powers of x the mean anomaly, is a problem requiring the aid of the higher analysis, and which it is unnecessary to investigate here. The following are a few of the first terms of the series, in which nt is substituted for x , n being the mean motion in the unit of time, and t the time elapsed since the passage through the perihelion:—

$$v = nt - \left(2e - \frac{1}{4}e^3 + \frac{5}{96}e^5 \right) \cdot \sin. nt \\ + \left(\frac{5}{4}e^2 - \frac{11}{24}e^4 + \frac{17}{192}e^6 \right) \sin. 2nt \\ - \left(\frac{13}{12}e^5 - \frac{43}{64}e^7 \right) \sin. 3nt \\ +, \&c.$$

*n's pa-
lax and
tance.* The form of the sun's orbit is discovered from the variations of his apparent diameter in passing from the perigee to the apogee; but in order to obtain a knowledge of its real dimensions, or of the mean distance of the sun from the earth, it is necessary to determine his parallax, that is to say, the angle subtended by the earth's semidiameter as seen from the sun. This angle is too small to be measured directly in the manner which was pointed out when treating of parallax; it is most accurately deduced from observations of the time occupied by an inferior planet in passing over the sun's disk, as will be explained afterwards. From such observations it has been found to be less than 9", an angle of which the sine is to radius in the ratio of 1 to 23,000 nearly; whence the distance of the sun is about 23,000 times the semidiameter of the earth. The following table exhibits more accurately the numerical results of calculation.

DISTANCE OF THE SUN FROM THE EARTH.		
	Semidiameters of the Earth.	English Miles.
In Perigee.....	23580	93280945
In Apogee.....	24388	96478967
At Mean Distance.....	23984	94879956
Greatest diameter of his orbit	47969	189764357

Theoretical Astronomy.

When the sun's parallax is known, we are enabled not only to estimate his distance, but also to compare his diameter and magnitude with those of the earth. For example, the mean parallax of the sun is 8".56; his mean apparent semidiameter, seen from the earth, is 961".4; the semidiameter of the sun and earth are therefore to each other in the ratio of 961.4 : 8.56, or of 112 to unity nearly. Supposing the sun and earth to be both spherical bodies, which is a supposition sufficiently accurate for the present purpose, their volumes will be to one another as the cubes of their radii; hence the volume of the sun is to that of the earth as the cube of 112 to unity, or the sun's volume is about 1,300,000 times greater than that of the earth.

SECT. III.—Of the Motion of Translation of the Earth, and the Aberration of Light.

Hitherto we have regarded the sun as being actually in motion round the earth in an elliptic orbit, of which the earth occupies one of the foci. This supposes the motion which we observe to be real. But we have already seen that all the phenomena of the diurnal revolution of the celestial bodies may be equally well explained by supposing these motions to be only optical illusions, of the same nature as those by which a person sailing rapidly along a river, or the sea-shore, is almost irresistibly led to ascribe the motion to the banks on the shore, even when fully aware that the appearance is only occasioned by his own motion in a contrary direction. In the same manner all the phenomena of the annual motion are susceptible of an equally simple explanation, on the hypothesis that the earth revolves in an elliptic orbit, and that the sun is at rest in one of the foci of the ellipse. In fact, if there were no other bodies in the universe than the earth and the sun, it would be matter of absolute indifference which of the two hypotheses we should adopt in order to explain the appearances. Supposing, for example, the earth to revolve in a circular orbit (the eccentricity, on account of its smallness, being here neglected), and the sun to be placed at the centre; a spectator at E (fig. 23) sees the sun S in the heavens at the point A, and corresponding to the star a on the celestial sphere. If the earth now take the place of the sun, and the sun be placed on the curve at A, the spectator will still see the sun correspond to the star a . Let the earth be transferred from E to E'; the spectator will then see the sun in A'. The sun therefore appears to him to have moved from A to A', which is exactly the same appearance as would be presented to a spectator at the centre by a real translation of S from A to A'; so that, in respect of the annual motion, the appearances, when referred to the celestial sphere, are precisely the same on either hypothesis.

If we now consider the phenomena with reference to the earth, we shall find that they may be all equally well explained on the hypothesis of the earth's motion, and the immobility of the sun. The most remarkable phenomenon connected with the annual revolution is the variation of the seasons; and in order to explain their cause, it is only necessary to suppose that the earth, in describing its oblique orbit, always preserves its axis parallel to the same straight line. Let A, B, C, D (fig. 24) repre-
Fig. 23.

Theoretical Astronomy. sent the earth in four different positions of its orbit, ns being its axis, and n and s its north and south poles respectively. While the earth goes round the sun in the order of the letters A, B, C, D, its axis ns preserves its obliquity, and always continues parallel to its first direction. At A the north pole inclines towards the sun, and brings all the northern places more into the light than at any other season of the year. But when the earth is at C, the opposite point of the orbit, the north pole declines from the sun, and a less portion of the northern hemisphere enjoys the blessings of his light and heat. At B and D the axis is perpendicular to the plane of the orbit, so that the poles are situated in the boundaries of the illuminated hemisphere, and the sun, being directly over the equator, makes the days and nights equal at all places. These phenomena are illustrated in fig. 25, which represents the situation of the north pole with regard to the limits of illumination, in eight different positions of the orbit. In this figure, $\mathcal{A}E$ is the terrestrial equator, T the tropic of Cancer, the dotted circle the parallel of London, U the arctic or north polar circle, and P the north pole, where all the meridians or hour-circles meet. The spectator is supposed to be placed at the pole of the ecliptic.

Plate
LXXXI.
Fig. 25.

When the earth is at the beginning of Libra, about the 20th of March, the sun, as seen from the earth, appears at the beginning of Aries in the opposite part of the heavens, the north pole is just coming into light, and the sun is vertical to the equator, which, with all its parallels, is divided into two equal parts by the circle which forms the boundary between the dark and illuminated hemispheres, and therefore the days and nights are equal all over the earth. As the earth moves in the ecliptic according to the order of the letters A, B, C, D, &c., the north pole P comes more and more into the light, and the days increase in length at all places north of the equator $\mathcal{A}E$. When the earth comes to the position between B and C, or the beginning of Capricorn, the sun, as seen from the earth, appears at the beginning of Cancer, about the 21st of June; and the north pole of the earth inclines towards the sun, so as to bring into light all the north frigid zone, and more of each of the northern parallels of latitude in proportion as they are farther from the equator. As the earth advances from Capricorn towards Aries, and the sun appears to move from Cancer towards Libra, the north pole recedes from the light, which causes the days to decrease and the nights to increase in length, till the earth comes to the beginning of Aries, and then they are equal as before; the boundary of light and darkness cutting the equator and all its parallels equally. The north pole then goes into the dark, and does not emerge till the earth has completed a semi-revolution of its orbit, or from the 23d of September till the 20th of March. All these phenomena will be readily understood from the bare inspection of the figure; and it will be perceived that what has been said of the northern hemisphere is equally true of the southern in a contrary sense, that is, at opposite seasons of the year.

The only objection against the annual motion of the earth, which at first sight creates some difficulty, is the enormous distance which, on account of the want of annual parallax, that hypothesis makes it necessary to assign to the fixed stars. Abstracting from the precession, which in the region of the poles amounts only to about $20''$, the axis of the earth, in every part of its orbit, appears to be directed towards the same point of the starry sphere. It is certain, however, that the radius of the terrestrial orbit is upwards of 90 millions of miles; and therefore, when the earth is at opposite points of this immense circle, its pole ought to be directed to points in the heavens 180

millions of miles distant from each other. Suppose the sun to be at rest in S (fig. 26), the centre of the orbit Eab , and the earth to be at the point E. Suppose also A to be the projection of S on the sphere of the fixed stars, and φ the first point of the ecliptic. The longitude of A, as seen from E, is the angle $AE\varphi$; but when seen from S, the longitude of the same point is $AS\varphi$. This last is the true longitude of A; $AE\varphi$ is the apparent longitude, and their difference is the angle $S\varphi E$. Now, in the first half of the ecliptic, the apparent longitude will be less than the true, and in the second half greater; hence there ought to result an apparent annual inequality in the sun's longitude. But as no such inequality is indicated by observation, it becomes necessary either to abandon the hypothesis of the earth's motion, or to suppose the distance of the fixed stars to be so great, that, in comparison of it, the radius ES, which exceeds 90 millions of miles, is altogether insensible; and that the whole orbit of the earth, or the ellipse Eab , is a mere point in comparison of a great circle of the starry sphere.

The most convincing proof of the earth's motion is not to be found in any circumstance of which the senses can take immediate cognizance, but is afforded by the full development of the planetary system, and the mutual connection of all the truths of rational astronomy,—by the clearness, simplicity, and coherence which this hypothesis gives to the most complicated phenomena,—and can therefore only be fully appreciated after an attentive study of the whole series of facts which astronomy makes known. There exists, however, one direct proof of the earth's annual motion, in a phenomenon discovered by the accurate observation and patient sagacity of Bradley, although it is one which, we are almost tempted to think, ought to have been perceived *a priori*, after Roemer's discovery of the progressive motion of light. It is known by the name of the *Aberration of Light*, and is manifested in a small difference between the apparent and true places of a star, occasioned by the motion of light combined with that of the earth in its orbit.

To illustrate this effect, conceive a body to move in the direction EE' (fig. 27), and another to impinge on it in the direction SE . To find the direction of the resulting motion, take EC and EA proportional to the two velocities respectively, and, having completed the parallelogram EABC, draw the diagonal EB. The combination of the two motions produces an impression on the eye exactly similar to that which would have been produced if the eye had remained at rest in the point E, and the molecule of light had come to it in the direction ES' ; the star, therefore, whose real place is at S, will appear to the spectator at E to be situated at S' . The difference between its true and apparent place, that is, the angle SES' , is the *aberration*, the magnitude of which is obtained from the known ratio of EA to EB, or the velocity of light to that of the earth in its orbit. Now, we know from the phenomena of the eclipses of Jupiter's satellites, that a ray of light describes a line equal to the mean radius of the ecliptic in 8 min. 13.2 sec. or 493.2 seconds of time. But the arc described by the earth in that time is found from the proportion

$$365^d.256 : 493^s.2 :: 360^\circ : x,$$

whence $x = 20''.25$. It is evident, therefore, that when the directions of the two motions are at right angles, the star S always appears in advance of its real place, in a direction parallel to that of the motion of the earth, by a quantity equal to $20''.25$. This quantity, $20''.25$, is called the *Constant of Aberration*; but as it has been obtained on the assumption that the earth moves uniformly in a circular orbit, it is evidently not altogether exact, and recourse

Theoretical Astronomy.
Fig. 26.

Aberration of Light

Fig. 27.

Theoretical must be had to observation to determine its precise amount. Bradley supposed it to be $20''$; Dr Brinkley, from the mean of 2633 comparisons of various stars, has deduced the value $20''.37$. From a series of 2000 observations of circumpolar stars, made for the purpose with the utmost care at the Greenwich Observatory by Mr Richardson, its value was found to be $20''.302$. On account of the number and accuracy of these observations, the constant of aberration may be regarded as one of the best determined elements of astronomy. (See *Memoirs of the Astronomical Society*, vol. iv.)

It is easy to see that, on the same principles, there ought also to be a diurnal aberration; but the diurnal rotation of the earth being sixty-five times less rapid than the orbital motion, its effect in producing aberration does not amount to more than $0''.0208$, when reduced to seconds of time. It is consequently altogether insensible in the observations.

The magnitude of the angle of deviation SES' depends on the relative directions of the earth and the visual ray, and may have any value from 0 to $20''.3$. Suppose, for example, we observe a star situated in the plane of the ecliptic. When the earth is at that point of its orbit, between the sun and the star, where the tangent to the orbit is perpendicular to the visual ray (which, on account that the star has no sensible parallax, always maintains a parallel direction), the apparent place of the star will be $20''.3$ to the eastward of its true place. When the earth is in the opposite point of its orbit the same star will appear to be $20''.3$ to the westward of its true place; so that it will appear to have an oscillatory motion on the ecliptic, the range of which is $40''.6$, and the period exactly a year. Half-way between these two points the tangent of the orbit is parallel to the direction of the ray of light, and consequently there is no aberration. When the star is not situated in the ecliptic, it will suffer a displacement in latitude as well as in longitude. To render this still more sensible, let EEE (fig. 28) be the ecliptic, E the earth, and A the true place of a star situated at any altitude above the ecliptic. In the direction EA take Ea to represent the velocity of light, ab that of the earth, and in a parallel direction, that is, parallel to the tangent to the ecliptic at E ; the line Eb will now be the apparent visual ray, and the star will seem to be situated at B . Suppose the earth to be placed at different points of its orbit; the lines Ea will be all parallel to each other on account of the infinite distance of the star A ; the lines ab will vary little in magnitude, because they are very small in comparison of Ea , but their directions will undergo every possible change, being always parallel to the tangent at E . At the two points of the orbit where the tangent is parallel to EA , the two lines Ea and ab coincide, and consequently there is no aberration. Let us next suppose the star to be situated in the pole of the ecliptic. In this case the visual ray is constantly perpendicular to the direction of the earth's motion, so that the star will always appear at a distance of $20''.3$ from its true place, or appear to describe a small circle about the pole of the ecliptic. In all other situations, out of the ecliptic, the star's apparent path will be an ellipse, the major axis of which, parallel to the plane of the ecliptic, is always $40''.6$, while the minor axis varies with the latitude.

The cause of the aberration being known, we have two methods of measuring its quantity, or the extent of the apparent oscillations, viz. by calculating the angle of deviation SAS' (fig. 27), the tangent of which is to radius as AB to AE , that is, as 1 to 10313; or, by direct observation, when the star is in opposition to the sun. The two methods give exactly the same result, and the dimensions

of the ellipse described by any star not situated in the ecliptic, in consequence of the aberration, are found to be the same when computed from theory or determined by direct observation. The motion of translation of the earth, therefore, receives a mathematical demonstration from this agreement; and the phenomenon of the aberration, otherwise unimportant on account of its minuteness, thus becomes one of the most interesting discoveries ever made in astronomy. The fact of the earth's orbital motion is, however, rendered so probable by other phenomena, that it must have been universally admitted, although the direct proof had never been discovered.

SECT. IV.—Of the Measure of Time. Equation of Time.

The notion of time, or of succession, is generally said to be acquired from the aspect of natural phenomena; but from whatever source it may be derived, it is certain that time itself can only be measured by comparing it with something of which the senses can take cognizance. If we have a series of events, such as the oscillations of a pendulum, or the flux and reflux of the sea, uniformly succeeding each other, then time may be measured by the number of such events that have been observed. In like manner, if a body move uniformly in a certain direction, time may be measured by the spaces over which it successively passes. In strict language, motion and time, being heterogeneous quantities, cannot measure one another; but different times are compared with each other by means of the motions that have taken place in those times respectively; for the motions being supposed uniform, equal spaces are passed over in equal times, or, which is the same thing, the times are directly proportional to the spaces described. If, therefore, we assume for unit the time which is absolved while a certain uniform motion takes place, we may obtain, by a simple proportion, the corresponding time of any other similar motion. In this manner we find the ratio of one portion of time to another, although we can form no idea whatever of its absolute quantity.

In order that motion may be employed as a measure of time, it is indispensably requisite that it be perfectly uniform. The only motions having this property, with which we are acquainted, are those of the rotation of the celestial bodies about their own axes. The motion of the sun and planets in their orbits is irregular from various causes: even the successive returns of the fixed stars to the meridian are rendered unequal on account of the precession and nutation; but the diurnal rotation of the earth appears to be affected by no cause of irregularity whatever. Time, therefore, may be properly measured by this uniform motion; and the method of proceeding is as follows. The culmination of a star, or of a given point of the equator, marks the instant at which the day commences, and at any other instant its horary angle determines the portion of the day which has elapsed at the moment of the observation. In order, therefore, to determine the time of an observation, we must find the horary angle formed by the meridian of the observed star with that which passes through the given point where the motion is supposed to begin; in other words, it is necessary to determine the star's right ascension. This, however, when attempted by direct measurement, is a determination attended with difficulty, and liable to considerable uncertainty. Happily the invention of the pendulum has rendered it unnecessary; and astronomers, instead of deducing the time from the right ascensions, determine, on the contrary, the right ascensions by means of the time indicated by the clock. The clock, of which the motion is supposed to be perfectly regular, is adjusted in such a

Theoretical manner that its index describes 24 hours, while a point of the equator describes an arc of 360° , or makes a complete revolution. This is called a *sidereal day*. The sidereal hour is divided in the usual manner into minutes, seconds, &c.; whence the corresponding arcs are easily found at the rate of 15° to an hour. The point whose culmination marks the origin of time is arbitrary; but astronomers have agreed to choose for that purpose the equinoctial point of Aries, from which the right ascensions are reckoned, so that the hours of the clock and the degrees of the equator may commence at the same instant. This point, it is true, is not, and cannot be, permanently marked by any star; but the right ascension in time of any star whatever being the hour of its transit over the meridian, the star will be in the plane of the meridian at the instant denoted by its right ascension in time. On this account sidereal time expresses the actual right ascension of the zenith; or, as it is frequently termed, the *right ascension of the mid-heaven*.

We have already seen, that on account of the precession of the equinoxes, a star employs somewhat more time than the first point of Aries in returning to the meridian. It is therefore not without some violation of language that the interval between two successive transits of a given point of the equator over the meridian is called a *sidereal day*, which, in its strict acceptation, denotes the time which elapses between two successive transits of the same star; but in this case the difference is so small as to be totally inappreciable. The annual precession in longitude is $= 50''.1$, and that in right ascension is nearly the same, excepting in regard to the circumpolar stars, which, therefore, are not employed in regulating the clocks. This arc of $50''.1$, converted into time, gives 3.3 seconds as the time in which a star will pass the meridian later than the equinoctial point, at the end of the year; and this small quantity being distributed over the whole year, is altogether insensible in short intervals of two or three days. The successive transits of a star, therefore, if we abstract from the nutation and aberration, will mark the sidereal day within the hundredth part of a second of time; and the sidereal year, though not immediately ascertainable by observation, becomes a quantity which may be easily computed. But the regularity of the motion of the stars is deranged by the effects of aberration and nutation; so that in order to measure time with the precision required by modern observers, it is necessary to be acquainted with the minute displacements of the stars. If they seem to return to the meridian after equal portions of absolute time, it is only because our organs are unable to distinguish the hundredths of a second.

The sidereal day is a measure of time which, on account of its uniformity and the facility of observing it, is excellently well adapted for astronomical purposes; but relatively to the ordinary wants of life it is not sufficiently marked;—the culmination of the stars is an event entirely unconnected with civil occupations, and which, for any given star, is even invisible during a great part of the year. The proper motion of the sun causes the sidereal day to commence sometimes by day and sometimes by night, so that great confusion and embarrassment would arise from regulating time and civil affairs by the motions of the stars. On this account the diurnal revolution of the sun has been universally adopted as the measure of time. This is called the *civil day*, and denotes the interval of time which elapses between two successive transits of the sun over the same hour-circle. Most nations have agreed in reckoning it from the inferior semicircle of the meridian, so that the civil day commences and terminates at midnight; but astronomers, in imita-

tion of Hipparchus and Ptolemy, usually reckon the commencement of the day from the instant of the sun's culmination, that is, from noon; and count through the 24 hours from one noon to the following. Thus 9 o'clock in the morning of February 14th is by astronomers called February the 13th at 21 hours. The day thus determined is called the *astronomical* or *solar day*; and being regulated by the true motion of the sun, the time which is measured by it is called *true* or *apparent* time.

Astronomical or solar days are not equal. Two causes, in particular, conspire to produce their inequality, namely, the unequal velocity of the sun in his orbit, and the obliquity of the ecliptic. The effect of the first cause is sufficiently sensible. At the summer solstice, when the sun's motion is slowest, the astronomical day approaches nearer the sidereal than at the winter solstice, when his motion is most rapid.

To conceive the effect of the second cause, it is necessary to have regard to the motion of the sun in reference to the equator. The sun describes every day a small arc of the ecliptic. Through the extremities of this arc suppose two meridians to pass; the arc of the equator, which they intercept, is the sun's motion for that day referred to the equator, and the time which that arc takes to pass the meridian is equal to the excess of the astronomical day above the sidereal. But it is obvious that at the equinoxes the arc of the equator is smaller than the corresponding arc of the ecliptic, in the proportion of the cosine of the obliquity of the ecliptic to radius: at the solstices, on the contrary, it is greater in the proportion of radius to the cosine of the same obliquity. The astronomical day is diminished in the first case, and lengthened in the second.

To have a mean astronomical day independent of these causes of inequality, astronomers have supposed a second sun to move uniformly on the ecliptic, and to pass over the extremities of the axis of the sun's orbit at the same instant with the real sun. This removes the inequality arising from the inequality of the sun's motion. To remove the inequality arising from the obliquity of the ecliptic, conceive a third sun to pass through the equinoxes at the same instant with the second sun, and to move along the equator in such a manner that the angular distances of the two suns at the vernal equinox shall be always equal. The interval between two consecutive returns of this third sun to the meridian forms the *mean astronomical day*. *Mean time* is measured by the number of the returns of this third sun to the meridian; and *true time* is measured by the number of returns of the real sun to the meridian. The arc of the equator, intercepted between two meridian circles drawn through the centres of the true sun and the imaginary third sun, when reduced to time, is what is called the *Equation of Time*. This will be rendered plainer by the following diagram.

Let $Z\varphi z$ (fig. 29) be the earth; $ZFRz$ its axis; $abede$, &c. the equator; $ABCDE$, &c. the northern half of the ecliptic from φ to z , on the side of the globe next the eye; and $MNOP$, &c. the southern half on the opposite side from z to φ . Let the points at A, B, C, D, E, F , &c. mark off equal portions of the ecliptic, gone through in equal times by the real sun, and those at a, b, c, d, e, f , &c. equal portions of the equator described in equal times by the fictitious sun; and let $Z\varphi z$ be the meridian.

As the real sun moves obliquely in the ecliptic, and the fictitious sun directly in the equator, any point between φ and F on the ecliptic must be nearer the meridian $Z\varphi z$, than the corresponding point on the equator from φ to f ; that is to say, than the point whose distance from φ is expressed by the same number of degrees; and the

more so, as the obliquity is greater; and therefore the true sun comes sooner to the meridian every day whilst he is in the quadrant φF , than the fictitious sun does in the quadrant φf ; for which reason the solar noon precedes noon by the clock, until the real sun comes to F , and the fictitious to f : which two points being equidistant from the meridian, both suns will come to it precisely at noon by the clock.

Whilst the real sun describes the second quadrant of the ecliptic $FGHIKL$ from Cancer to $\triangle$, he comes later to the meridian every day than the fictitious sun moving through the second quadrant of the equator from f to $\triangle$; for the points at G, H, I, K, L , being farther from the meridian, their corresponding points at g, h, i, k, l , must come to it later; and as both suns come at the same moment to the point W , they come to the meridian at the moment of noon by the clock.

In departing from $Libra$ through the third quadrant, the real sun going through $MNOPQ$ towards φ at R , and the fictitious sun through $mnopq$ towards r , the former comes to the meridian every day sooner than the latter, until the real sun comes to R , and the fictitious to r , and then they come both to the meridian at the same time.

Lastly, as the real sun moves equably through $STUVW$, from R towards φ , and the fictitious sun through $stuvw$, from r towards φ , the former comes later every day to the meridian than the latter, until they both arrive at the point φ , and then they make it noon at the same time with the clock.

Having explained one cause of the difference between true and mean time, we now proceed to explain the other cause of this difference, namely, the inequality of the sun's apparent motion, which is slowest in summer, when the sun is farthest from the earth, and swiftest in winter, when he is nearest to it.

If the sun's motion were equable in the ecliptic, the whole difference between the equal time as shown by the clock, and the unequal time as shown by the sun, would arise from the obliquity of the ecliptic. But the sun's motion sometimes exceeds a degree in 24 hours, though generally it is less; and when his motion is slowest, any particular meridian will revolve sooner to him than when his motion is quickest; for it will overtake him in less time when he advances a less space than when he moves through a larger.

Now, if there were two suns moving in the plane of the ecliptic, so as to go round it in a year, the one describing an equal arc every 24 hours, and the other describing in the same time sometimes a less arc, and at other times a larger, gaining at one time of the year what it lost at the opposite; it is evident that one of these suns would come sooner or later to the meridian than the other, as it happened to be behind or before the other; and when they were in conjunction, they would both come to the meridian at the same moment.

As the real sun moves unequably in the ecliptic, let us suppose a fictitious sun to move equably in a circle coincident with the plane of the ecliptic. Let $ABCD$ (fig. 30) be the ecliptic or orbit in which the real sun moves, and the dotted circle $abcd$ the imaginary orbit of the fictitious sun; each going round in a year according to the order of letters, or from west to east. Let $HIKL$ be the earth turning round its axis in the same direction every 24 hours; and suppose the two suns to start from A and a , at the same moment, A and a being in the same straight line, and in the plane of the meridian EH . Suppose also that the real sun, when at A , is at his greatest distance from the earth, where his motion is slowest. In the time that the meridian revolves from H to H again, according to the

order of the letters $HIKL$, the real sun has moved from A to F ; and the fictitious sun with a quicker motion from a to f , through a larger arc: therefore the meridian EH will revolve sooner from H to h under the real sun at F , than from HE to h under the fictitious sun at f ; and consequently it will then be noon by the sun-dial sooner than by the clock.

As the real sun moves from A towards C , the velocity of his motion increases all the way to C , where it is at its maximum. But notwithstanding this, the fictitious sun gains so much upon the real, soon after his departing from A , that the increasing velocity of the real sun does not bring him up with the equally-moving fictitious sun till the former comes to C and the latter to c , when each has gone half round its respective orbit; and then being in conjunction, the meridian EH , revolving to EK , comes to both suns at the same time, and therefore it is noon by them both at the same moment.

But the increased velocity of the real sun now being at its maximum, carries him before the fictitious one; and therefore the same meridian will come to the fictitious sun sooner than to the real; for whilst the fictitious sun moves from c to g , the real sun moves through a greater arc from C to G ; consequently the point K has its noon by the clock when it comes to k , but not its noon by the sun till it comes to l . And although the velocity of the real sun diminishes all the way from C to A , and the fictitious sun by an equable motion is still coming nearer to the real sun, yet they are not in conjunction till the one comes to A and the other to a , and then it is noon by them both at the same moment.

Mean solar time and sidereal time being both uniform, it is easy to compare the one with the other, and assign the number of degrees, minutes, &c. which the sun and a star will respectively describe in a given portion of sidereal or mean solar time. In a mean solar day the sun's right ascension and mean longitude are increased by $59^{\circ} 8' 33''$; consequently $360^{\circ} 59' 8'' 33''$ of the equator pass the meridian in 24 mean solar hours. The sidereal time corresponding to this period is 24 hours 3 min. 56.555 sec.; therefore 24 mean solar hours are equal to 24 hours 3 min. 56.555 sec. of sidereal time; and 24 hours of sidereal time are equal to 23 hours 56 min. 4.0907 sec. of mean solar time, or to 24 hours minus 3 min. 55.9093 sec. This difference of 3 min. 55.9093 sec. is called the *acceleration of the fixed stars* in mean solar time; and the preceding excess of 3 min. 56.555 sec. is the retardation of the sun in sidereal time. Hence the one species of time may be easily converted into the other; and the arc of the equator passed over by the meridian in a given mean time may be calculated. Thus,

$$\frac{360^{\circ} 59' 8'' 33''}{24} = 15^{\circ} 2' 27'' 84708$$

is the arc described by a star in one hour of mean solar time.

But the process of converting sidereal or mean solar time into true or apparent time, or of computing from the instants of apparent time the corresponding mean solar and sidereal times, is attended with much greater difficulty. The reason is, that the interval between two successive transits of the sun over the meridian, which, in apparent time, measures the day, is a variable quantity; and hence there cannot exist any constant ratio between true and mean time, as there does between mean and sidereal time. The correction or equation by which apparent time is reduced to mean time, is technically called the *Equation of Time*, and is composed of the aggregate of the several variable terms which denote the inequalities of the sun's motion in longitude. Besides the eccentricity,

Theoretical Astronomy. the obliquity of the ecliptic, and the variations of that obliquity occasioned by the nutation of the earth's axis, it is affected also by the small alterations of the sun's right ascension, which result from the effect of the planetary perturbations on the earth; and hence the equation of time cannot be exactly computed without the aid of Physical Astronomy.

It will be evident, from what has preceded, that the equation of time expresses merely the difference between the true and mean right ascensions of the sun, reduced to time. Its different parts may be calculated numerically in the following manner. Let NA (fig. 31) represent the mean motion of the sun during a given interval, then NA is the sun's mean longitude, N being the first point of Aries. Let NA = M, and from this mean longitude subtract the longitude of the apogee, the remainder will be the sun's mean anomaly. From the mean anomaly let the equation of the centre be found and denoted by E. Take AB = E, then NB = M + E is the longitude corrected for the eccentricity.

Fig. 31.

Let us next suppose BC to be the small quantity by which the sun's longitude is increased in consequence of the perturbations of the planets, and let BC = P; then NC = M + E + P is the true and exact longitude of the sun. Through C let the arc CD be drawn perpendicular to the equator; the point D will be that point of the equator which passes the meridian at the same time with the sun. Let R = NC — ND = the reduction to the ecliptic; we have then the sun's right ascension = M + E + P — R.

Let NF = NA, and F will be the place which the sun would occupy in the equator at the same instant that he occupies the point A in the ecliptic, if he moved uniformly in the former circle; for NF as well as NA will represent the mean diurnal motion of 59' 8".33 multiplied by the number of days elapsed in the interval between the equinox N and the time of the observation. The mean sun would therefore pass the meridian with the point F, whereas the true sun passes it with the point D; therefore, at the instant of true noon, when the sun C and the corresponding point D are on the meridian, the mean sun is at a distance from D expressed by the arc FD = M + E + P — R — M = E + P — R. Now, the arc of the equator FD measures the horary angle between the mean and the true sun, or the angle at the pole between the meridian and the hour-circle passing through D; it is therefore converted into time by the following proportion:—

360° : FD :: 24 mean solar hours : time from true noon; consequently the difference between mean and true noon, or the equation of time,

$$= \frac{FD \times 24^h}{360^\circ} = \frac{1}{15}(E + P - R) = dT.$$

But this equation is not yet perfectly accurate: it requires to be corrected for the effects of nutation. Now it is known that the variation of the mean longitude of the sun, arising from the unequal precession of the equinoxes in consequence of the nutation occasioned by the inclination of the lunar orbit, is expressed by the formula 18" sin. (360° — moon's node) = 18" sin. N. This variation, reduced to the direction of the equator, will therefore be 18" sin. N cos. e (e being the obliquity of the ecliptic). The difference between the two expressions is 18" sin. N (1 — cos. e) = 36" sin.² $\frac{1}{2}$ e sin. N = 1".4887 sin. N, which, reduced to time, becomes 0.09925 sec. × sin. N. This small correction, amounting to less than a tenth of a second, was long omitted in computing the equation of time. When it is included, that equation becomes

$$dT = \frac{1}{60}(E + P - R) + 0.09925 \text{ sec.} \times \sin. N.$$

The quantities E, P, R, and N, are to be computed separately from the astronomical tables; and it must be observed, that the result will be expressed in mean solar time.

The cosine of the obliquity, that is, cos. 23° 28', is equal to .9173 = $\frac{1}{2}$ very nearly. Hence, since the equation of time is equal to the sun's true right ascension, diminished by his mean longitude and the effects of nutation in right ascension (= ND — NA = 18" sin. N cos. e), it may, on denoting the true right ascension by A, be expressed as follows:—

$$dT = A - M \mp 18" \sin. N \times \frac{1}{12}.$$

This is the form under which the equation of time was expressed by Dr Maskelyne.

The equation of time is at its maximum about the 3d of November, when it amounts to 16' 16".7, and is subtractive. At four different times of the year it vanishes, namely, about the 25th of December, the 16th of April, the 16th of June, and the 1st of September. These epochs, however, do not remain constant; for, on account of the change which the line of the apsidæ is constantly undergoing in reference to the line of the equinoxes, the difference between the true and mean right ascensions of the sun—in other words, the equation of time—varies continually in different years.

SECT. V.—Of the Spots of the Sun, his Rotation, and Constitution.

The sun, the great source of light, heat, and animation, when beheld with the naked eye, appears only as a luminous mass of uniform splendour and brightness; but when examined with the telescope, his surface is frequently observed to be mottled over with a number of dark spots, of irregular and ill-defined forms, and constantly varying in appearance, situation, and magnitude. These spots are occasionally of immense size, so as to be even visible without the aid of the telescope; and their number is frequently so great that they occupy a considerable portion of the sun's surface. Dr Herschel observed one in 1779, the diameter of which exceeded 50,000 miles, more than six times the diameter of the earth; and Scheiner affirms that he has seen no less than 50 on the sun's disk at once. Most of them have a deep black nucleus, surrounded by a fainter shade, or *umbra*, of which the inner part, nearest to the nucleus, is brighter than the exterior portion. The boundary between the nucleus and umbra is in general tolerably well defined; and beyond the umbra a stripe of light appears more vivid than the rest of the sun.

The discovery of the sun's spots has been attributed to different astronomers. They appear to have been first taken notice of in a work of Fabricius, the friend of Kepler, which was published at Wittenberg in 1611, under the title of *Joh. Fabricii Phrysi de Maculis in Sole Observatis, et Apparente earum cum Sole Conversione Narratio*. It contains, however, nothing more than a few vague conjectures respecting the spots, the phenomena of which he could not have observed with any degree of accuracy, inasmuch as he seems to have been unacquainted with any method of protecting the eye by intercepting a portion of the solar rays; for he recommends to those who should repeat his observations, to admit into the telescope only a small portion of the sun at once, till the eye should by degrees become able to support the full blaze of light. About the same time the discovery was warmly disputed by the illustrious Galileo, and Schciner, a German Jesuit, professor of mathematics at Ingolstadt. The whole circumstances connected with this dispute are narrated at great length by Galileo in his work entitled *Istoria e Di-*

Theoretical Astronomy. *mostrazioni intorno alle Macchie Solari, e loro Accidenti*, from which it appears certain that he observed the spots so early as April 1611. In a letter published by him in 1612, he remarks that the spots are situated on the surface of the sun, or that at least their distance from it is imperceptible; that the time of their continuance varies from 2 or 3 to 30 or 40 days; that their figures are irregular and variable; that some are seen to separate, and others to unite, even on the middle of the disk; that besides these peculiar motions, they have also a common motion, in virtue of which they traverse the disk in parallel lines. From this general motion he infers that the sun turns on an axis from west to east; and he adds as a curious remark, that the spots are confined within a zone extending only about 28 or 29 degrees to the north and south of the sun's equator. Galileo illustrates all these positions by mathematical reasoning, and by drawings of the spots made on many successive days.

Scheiner's observations were first announced in January 1612, in three letters addressed to his friend Marc Velsper, a magistrate of Augsburg. In the first of these, the date of which is November 1611, he says that he had observed the spots seven months before, but that, having a different object in view, he had given little attention to them. He observed them again in the following October, and at that time imagined the appearance was owing to some imperfection of his telescope, till he was convinced by repeated observations that it was necessary to refer it to the sun. From these remarks it is pretty clear that Scheiner had formed no accurate notions respecting the spots before October 1611, that is, six months after they had been observed by Galileo. Scheiner made the observation of the solar spots his whole occupation during the following eighteen years, in the course of which he discovered the position of the solar equator, and formed a theory much more complete than that of Galileo. The account of his observations was published in 1630, under the title of *Rosa Ursina, sive Sol ex admirando Facularum et Macularum suarum Phenomeno Varius, &c.*

The discovery of the solar spots has also been claimed for our countryman Harriot. Amidst these conflicting pretensions it is perhaps impossible to arrive at the truth; but the matter is of little importance; the discovery is one which followed inevitably that of the telescope, and an accidental priority of observation can hardly be considered as establishing any claim to merit.

The solar spots furnish an extensive subject of curious speculation, but in an astronomical point of view they are chiefly interesting on account of their establishing the fact, and affording the means of determining the period, of the rotation of the sun. In order to obtain a precise idea of the position of a spot, and the path which it describes, it is necessary to project that path on the plane passing through the centre of the sun, and perpendicular to the visual ray drawn from the earth to the sun's centre. Suppose the diameter of a circle ASB (fig. 32) to be divided into as many parts of unity as there are seconds in the apparent diameter of the sun. Let CP be taken equal to the number of seconds contained in the difference of the longitudes of the spot and the sun's centre, and the perpendicular PM equal to the number of seconds in the latitude of the spot; then M will represent its position on the surface of the sun. By repeating the same operation a number of days consecutively, a series of points M M' M'', &c. will be obtained in the apparent path of the spot on the sun's disk, or rather in the projection of that path on the plane perpendicular to the visual ray. This projection is in general an oval slightly differing from an ellipse; and it is found that all the spots observed at

Theoretical Astronomy. the same time describe similar and parallel curves. They also return to the same relative positions in the same time, and their period is about 27 $\frac{1}{2}$ days.

The paths described by the spots undergo very considerable changes, according to the season of the year at which they are observed. About the end of November and beginning of December they appear simply as straight lines Mm, M'm', M''m'' (fig. 33), along which the spots move in the direction Mm, that is, they enter on the eastern and disappear on the western edge of the sun's disk; and the points at which they disappear are more elevated, or nearer the north pole of the ecliptic, than those at which they enter. After a certain time the lines Mm begin to assume a curved appearance, and form ovals, as represented in fig. 34. During the winter and spring the convexity of the ovals is turned towards the north pole of the ecliptic; but their inclination, or rather the inclination of the straight lines joining their extreme points, to the plane of the ecliptic continues to diminish, and about the beginning of March disappears; so that the points at which they seem to enter and leave the sun's disk are equally elevated, as in fig. 35. From this time the curvature of the ovals diminishes; they become narrower and narrower till about the end of May or beginning of June, when they again appear under the form of straight lines (fig. 36); but their inclinations to the ecliptic are now precisely in a contrary direction to what they were six months before. After this they begin again to expand, as in fig. 37, and their convexity is now turned towards the south pole. Their inclinations also vary at the same time, and about the commencement of September they are seen as represented in fig. 38; the points at which they enter and disappear being again equally elevated. After this period the ovals begin to contract and become inclined to the ecliptic, and by the beginning of December they have exactly the same direction and inclination as they had the previous year.

These phenomena are renewed every year in the same order, and the same phases are always exhibited at corresponding seasons. Hence it is evident that they depend on a uniform and regular cause, which is common to all of them, since the orbits described by the various spots are exactly parallel, and subject in all respects to the same variations. The simplest method of explaining the phenomena is to suppose with Galileo that the spots are adherent to the surface of the sun, and that the sun uniformly revolves round an axis inclined to the axis of the ecliptic. If the axis of revolution were perpendicular to the plane of the ecliptic, the spots, supposing them to adhere to the sun's surface, would describe circles parallel to that plane, which, seen from the earth, would appear as so many parallel straight lines; but by supposing the axis to have a suitable inclination, all the phenomena become explicable in a very simple manner. While the sun is carried round in his orbit, his axis, constantly preserving its parallelism, will successively assume different positions relatively to the earth; and the planes of the circles described by the spots, which planes are always perpendicular to the axis, will consequently be presented to us under different inclinations; hence the variations of their apparent curvature. In two opposite points of the orbit the visual ray drawn from the earth to the centre of the sun is perpendicular to the axis of rotation. In these two positions the poles of the sun, or the points in which the axis meets the surface, are both visible at the same moment, and the spots appear to move in parallel straight lines. But as the axis retains this perpendicular position only for an instant, and declines from it very sensibly while the spot traverses the sun's disk, the path of

Theoretical
Astronomy.

the spots over the entire disk is neither a straight line nor an ellipse, one of which it would necessarily be if the sun, while revolving about his axis, did not change his place in his orbit. When the axis is not perpendicular to the visual ray, the path of the spots will appear to be a curve of which the concavity is turned towards that pole which is visible from the earth. This inclination of the solar axis to the plane of the ecliptic also explains the reason why the points of the disk at which the spots appear are more elevated during one half of the year, and more depressed during the other half, than those at which they disappear. It will also follow from the same hypothesis, that the curvature of the ovals must be the greatest possible when the straight lines joining their extremities are parallel to the ecliptic; and, on the contrary, least when the same straight lines are most inclined to the ecliptic; all which is exactly conformable to observation.

The various appearances which we have now described may be accurately represented by means of a common celestial or terrestrial globe. Let the wooden horizon of the globe, which is here supposed to represent the sun, be placed horizontally in the same plane with the eye of the spectator, and the pole be inclined about 7° from the zenith. The wooden horizon will now represent the ecliptic; and if the spectator walk round the globe, always keeping his eye in the plane of the wooden horizon, the circles of latitude will appear to him as ellipses of different inclinations and eccentricities: in two opposite points they will appear as straight lines, and, in short, exhibit in their various positions all the phenomena of the oval paths described by the spots of the sun.

The consequences deduced from the hypothesis of the rotatory motion of the sun are so perfectly conformable with observation, as to render the inference inevitable, that *the sun revolves from west to east, on an axis inclined about 93° to the plane of the ecliptic.* The plane which passes through the centre of the sun, perpendicular to the axis of rotation, is the *Equator* of the sun; the straight line joining the points in which it intersects the ecliptic is called the *Line of the Nodes* of the equator. The *Nodes* themselves are the two opposite points in which this straight line, produced indefinitely, meets the celestial sphere.

In order to determine the situation of the solar axis in space, it is necessary to find its inclination to the ecliptic, and the angle which the line of the nodes makes with any given line on the plane of the ecliptic, for example, with the line of the equinoxes. The requisite data for the solution of this problem are three different positions of the same spot, which must be obtained by observation. Let S (fig. 39) be the centre of the sun's disk, AB a parallel to the terrestrial equator, and M the place of a spot, the co-ordinates of which, as referred to AB, are SX and MX. In this figure the earth is supposed to be situated in a straight line passing through S perpendicular to the plane of the paper, and it is to be recollected that SX and MX are in fact arcs of the solar globe, though so small when seen from the earth that they may be regarded as straight lines. By comparing the times of the transits of B, the border of the disk, and the spot M, we shall find BX, from which, as SB the semidiameter of the sun is known, we shall have SX the difference of the right ascensions of the spot and sun's centre. The line CY, which is the difference of the declination of the border of the disk and that of the spot, is measured by the micrometer. This will give MX the declination of the spot.

Now, $\tan. MSX = \frac{MX}{SX}$, and $SM = \frac{SX}{\cos. MSX}$; therefore SM is also a known quantity. Let EE be the ecliptic,

e = obliquity of the ecliptic, and $\odot$ = the longitude of the sun. The angle BSE, which is technically called the *Angle of Position*, is the complement of the angle made by the ecliptic with the circle of declination passing through the sun, and is therefore given by the formula $\tan. BSE = \tan. e \cos. \odot$: hence MSE (= MSX — BSE) is also given. On SE let fall the perpendicular Mm, then $Mm = SM \sin. MSE$ is the geocentric latitude of the spot, and $Sm = SM \cos. MSE$ is the difference between its geocentric longitude and that of the centre of the sun: the object is now to determine the angles subtended by these lines at the centre of the sun, that is, to convert the *geocentric* into *heliocentric* latitudes and longitudes.

Suppose two straight lines to be drawn from the earth, one to the centre of the sun, and the other to the centre of the spot M, and let θ be their inclination, which is measured by SM, and is consequently known, being the geocentric distance of the spot from S, the centre of the sun's disk. Let R = distance of the sun's centre from the earth, r = semidiameter of the sun, ϕ = the angle made at the centre of the sun by the straight lines drawn from it to the earth and the spot M, and let ψ be the remaining angle of the triangle formed by the lines joining the earth, the centre of the sun, and the spot. We have then $r : R :: \sin. \theta : \sin. \psi$, whence $\sin. \psi = \frac{r}{R} \sin. \theta$. But R : r as radius to the sine of half the sun's

true diameter; therefore $\sin. \psi = \frac{\sin. \theta}{\sin. \frac{1}{2} \text{ sun's diameter}}$.

Now $\phi = 180^\circ - \psi - \theta$, consequently we have the number of degrees, minutes, and seconds in ϕ , the heliocentric distance of the spot from the straight line which joins the centres of the earth and sun. Having thus obtained the hypothenuse SM in parts of a great circle of the solar orb, the sides Sm and Mm will be obtained in similar parts from the common trigonometrical formulæ for the resolution of a right-angled spherical triangle. These formulæ give

$$\begin{aligned} \tan. Sm &= \tan. SM \cos. MSE, \\ \sin. Mm &= \sin. SM \sin. MSE. \end{aligned}$$

It will be remarked that Mm is the heliocentric latitude of the spot, Sm the difference of its longitude and that of the earth; and as the longitude of the earth is equal to $180^\circ +$ that of the sun, the heliocentric longitude of the spot will be $180^\circ + \odot - SM$ if the spot is behind or to the east of the centre of the sun, and $180^\circ + \odot + Sm$ if it precedes the centre.

In this manner the heliocentric longitudes and latitudes of the spots are deduced from their observed right ascensions and declinations. The next step is to show how they are employed in determining the position of the solar axis. This problem is in practice somewhat laborious, although the principles on which its solution rests are sufficiently simple. The planes of the circles described by the spots are parallel to the sun's equator: if, therefore, the position of one of them can be found, the position of the equator, and consequently of the axis, will be found at the same time. Now, the position of a plane is determined by three given points through which it is required to pass; consequently, by three observations of the same spot, we shall have three points in its plane, and thence the plane itself. The problem is therefore one of pure geometry, and may be solved in various ways. The results of the most accurate observations make the inclination of the solar equator to the ecliptic amount to $7^\circ 19' 23''$ or, $7^\circ \frac{1}{2}$ very nearly; and the heliocentric longitude of the ascending node, that is, the point in which the equator of the sun intersects the ecliptic, in passing from

Fig. 39.

Theoretical south to north, $80^{\circ} 7' 4''$. The position of the node seems to undergo no variation, except such as may be supposed to arise from the precession of the equinoxes.

It has already been mentioned that the mean time in which a solar spot returns to the same position, relatively to the earth, is 27.3 days. This, however, is not the time in which the sun makes a revolution about his axis. In the interval of 27.3 days the sun describes in the ecliptic an arc equal to $26^{\circ} 91'$ (for $365^d 25' : 27^d 3' :: 360^{\circ} : 26^{\circ} 91'$), and by virtue of this motion alone he exhibits every day different points of his surface, the whole of which would be successively shown to the earth in the course of a year, independently of the motion of rotation. Hence results an apparent annual rotation round an axis perpendicular to the ecliptic, and we must abstract the effects of this optical illusion in order to arrive at the time of a real rotation. This apparent rotatory motion will be easily understood by referring to fig. 40, in which S is the sun, E the earth, and C the point in which the visual ray ES intersects the surface of the sun. Suppose the sun to have advanced in his orbit from S to S', the visual ray drawn from the sun's centre to the earth will now meet the surface in a different point C', and the angular distance between C and C' will be found by drawing S'E' parallel to SE; for the point e in which S'E meets the surface will correspond to C, and the arc C'e, or the angle E'S'E, will be the apparent rotation, while the sun advances in his orbit from S to S'. Now, the angle E'S'E is equal to S'ES, or the apparent rotatory motion is equal to the angular motion of the sun in his orbit; hence, since the real rotation is in a contrary direction, it is obvious that, if the axis were perpendicular to the plane of the ecliptic, when a spot appears to have made one revolution, it has in reality passed over an arc equal to $360^{\circ} + 26^{\circ} 91'$, or $386^{\circ} 91'$ degrees. By a simple proportion, therefore,

$$386.91 : 360 :: 27.3 : 25.4;$$

and consequently 25.4 days is the real time of the sun's revolution. This result is, however, not quite accurate, on account of its having been supposed that the axis of rotation is perpendicular to the ecliptic, whereas it differs from a perpendicular to that plane by $7^{\circ} \frac{1}{2}$; but the correction necessary on account of the difference is so small as to fall far within the limits of the errors to which the observations are liable; it is therefore unnecessary to have regard to it.

Observations of the spots, from which the elements of the sun's rotation are deduced, are attended with a very considerable degree of uncertainty. The semidiameter of the sun, which at the surface of the earth subtends an angle of only $16'$, or $960''$, is equivalent to 90° at the centre of the sun. Hence the error of a single second (and it is impossible to answer for one or two seconds in observations of this sort) corresponds to about $338''$, or $5' 38''$, on the surface of the solar globe. An observer may, therefore, notwithstanding the greatest care, be mistaken to the extent of $10'$ with regard to the length of a heliocentric arc; and when to this we add, that the margins of the spots are ill defined, and even changeable, so that their centres, which it becomes necessary to observe, are not always the same, it will not appear surprising that a considerable discordance exists among the results of different observations. The uncertainty respecting the time of rotation amounts to no less than 10 or 12 hours. From a careful discussion of a numerous set of observations, Delambre found the time of rotation to be only 25.01154 days, instead of 25.4 given above; and he remarks that, in order to render the last-mentioned number admissible, it is necessary to suppose either an error of $2^{\circ} 22'$, which is scarcely possible, or else that the spot has a proper mo-

tion in the same direction as the motion of rotation of the earth and all the planets.

From four different combinations of equations, derived from eleven observations of the same spot, Delambre computed the following table of the elements of rotation.

	Node.	Inclination.	Revolution.	Synodic Revol.
1	$80^{\circ} 45' 7''$	$7^{\circ} 19' 17''$	$25^d 0^h 17^m$	$26^d 4^h 17^m$
2	$79 21 35$	$7 12 37$		
3	$80 33 40$	$7 16 33$		
4	$79 47 55$	$7 29 4$		
	$80 7 4$	$7 19 23$	Diurnal motion $14^{\circ} 39'$	

With regard to observations on the sun's spots, Delambre remarks that he attaches little value to them, first, because it is impossible to make them well; and, secondly, because, even if they were sure, they only lead to results of little importance to astronomy. He discussed a hundred different spots, each observed at least three times by Messier, and deduced thirty different determinations of the elements of rotation. The more he multiplied his calculations, the more certain he became of the impossibility of a good solution; of which, indeed, there is no other chance than in a compensation of errors, little probable on account of their enormous magnitudes. These discrepancies render it probable that the spots, besides partaking of the general motion of the solar globe, have also proper motions either of displacement, or occasioned by a change of form, which may long prevent this part of astronomy from reaching a greater degree of exactness than it has already attained.

From the circumstance that the sun is incontestably endowed with a rotatory motion, Lalande concluded that, according to the rules of probability, he ought also to have a motion of translation in space. This idea was adopted by Herschel, and is now generally received as probable. It explains some, though not all, of the proper motions which have been supposed to be observed among the stars. If, indeed, the stars are so many suns, revolving like ours each on its own axis of rotation, it is extremely probable that they have also motions of translation; and thus, there being no fixed points in the heavens, the problem of their proper motions becomes so complicated as to be altogether insoluble.

The only interesting fact which has been deduced from the observations of the solar spots is the rotation of the sun. The curious appearances which they exhibit have, however, attracted great attention, and given rise to numerous theories respecting the constitution of that immense body which governs and vivifies the planetary system. We will now proceed to give a brief account of the appearances, and mention some of the theories that have been founded on them; premising, that after all that has been written on this subject, we are not yet, and probably never will be, in possession of any definite knowledge. The nature of the spots, and the physical constitution of the sun, afford fruitful subjects of harmless conjecture and speculation, but form no part of science.

The phenomena of the solar spots, as delivered by Appearances of Scheiner and Hevelius, may be summed up in the following particulars. 1. Every spot which has a nucleus, or comparatively dark part, has also an umbra, or fainter shade surrounding it. 2. The boundary between the nucleus and umbra is always distinct and well defined. 3. The increase of a spot is gradual, the breadth of the nucleus and umbra dilating at the same time. 4. In like manner the decrease of a spot is gradual, the breadth of the nucleus and umbra contracting at the same time.

Theoretical Astronomy. 5. The exterior boundary of the umbra never consists of sharp angles, but is always curvilinear, how irregular soever the outline of the nucleus may be. 6. The nucleus of a spot, whilst on the decrease, often changes its figure by the umbra encroaching irregularly upon it, inasmuch that in a small space of time new encroachments are discernible, whereby the boundary between the nucleus and umbra is perpetually varying. 7. It often happens, by these encroachments, that the nucleus of a spot is divided into two or more nuclei. 8. The nuclei of the spots vanish sooner than the umbra. 9. Small umbræ are often seen without nuclei. 10. An umbra of any considerable size is seldom seen without a nucleus in the middle of it. 11. When a spot which consisted of a nucleus and umbra is about to disappear, if it is not succeeded by a *facula* or spot brighter than the rest of the disk, the place where it was is soon after not distinguishable from the rest.

In the *Philosophical Transactions*, vol. lxiv. Dr Wilson, late professor of astronomy at Glasgow, has given a dissertation on the nature of the solar spots, in which he mentions the following appearances. 1. When the spot is about to disappear on the western edge of the sun's limb, the eastern part of the umbra first contracts, then vanishes, the nucleus and western part of the umbra remaining; then the nucleus gradually contracts and vanishes, while the western part only of the umbra remains. At last this disappears also; and if the spot remains long enough to become again visible, the eastern part of the umbra first becomes visible, then the nucleus; and when the spot approaches the middle of the disk, the nucleus appears environed by the umbra on all sides, as already mentioned. 2. When two spots lie very near to one another, the umbra is deficient on that side which lies next to the other spot: and this will be the case, though a large spot should be contiguous to one much smaller; the umbra of the large spot will be totally wanting on that side next the small one. If there are little spots on each side of the large one, the umbra does not totally vanish, but appears flattened or pressed in towards the nucleus on each side. When the little spots disappear, the umbra of the large one extends itself as usual. This circumstance, he observes, may sometimes prevent the disappearance of the umbra in the manner above mentioned; so that the western umbra may disappear before the nucleus, if a small spot happens to break out on that side.

In the same volume, p. 337, the Rev. Dr Wollaston observes that the appearances mentioned by Dr Wilson are not uniform. He positively affirms that the *faculæ* or bright spots on the sun are often converted into dark ones. "I have many times," says he, "observed near the eastern limb a bright *facula* just come on, which has the next day shown itself as a spot, though I do not recollect to have seen such a *facula* near the western one after a spot's disappearance. Yet, I believe, both these circumstances have been observed by others, and perhaps not only near the limbs. The circumstance of the *faculæ* being converted into spots, I think I may be sure of. That there is generally, perhaps always, a mottled appearance over the face of the sun, when carefully attended to, I think I may be as certain. It is most visible towards the limbs, but I have undoubtedly seen it in the centre; yet I do not recollect to have observed this appearance, or indeed any spots, towards the poles. Once I saw, with a twelve-inch reflector, a spot burst to pieces while I was looking at it. I could not expect such an event, and therefore cannot be certain of the exact particulars; but the appearance, as it struck me at the time, was like that of a piece of ice when dashed on a frozen pond, which breaks to pieces and slides in various directions." He also

observes, that the nuclei of the spots are not always in the middle of the umbræ, and gives the figure of one seen on the 13th of November 1773, which is a remarkable instance to the contrary.

The *faculæ*, or bright spots, were observed with particular attention by Messier, who frequently saw them enter on the eastern limb of the sun, disappear as they approached the centre of the disk, re-appear on the opposite limb, and continue visible, as they had done at the time of their first appearance, for about three days, till they were carried off the disk by the rotation of the sun. Spots frequently broke out in these *faculæ*, and when this did not happen, they were succeeded by spots which generally became visible on the following day; and from the regularity of this occurrence, he was enabled to predict the appearance of a spot 24 hours before it entered on the sun's disk. He observed, also, that the magnitude of the spots was proportional to the brightness of the antecedent *faculæ*. Like the spots, the *faculæ* are generally confined to the equatorial regions of the sun; but they have been occasionally observed by Schroeter on every part of the disk.

To explain these singular appearances, numerous theories, more or less plausible, have been proposed, but all resting on many gratuitous assumptions, and subject to great difficulties. Scheiner imagined that the spots do not belong to the sun, but supposed them to be inferior planets revolving at no great distance from the central luminary. Galileo, Hevelius, and others, have supposed them to be *scoriæ* floating in the inflammable liquid matter of which they imagined the sun to be composed. This opinion, although it accounts for the appearance of the spots in the equatorial regions of the sun, to which such *scoriæ* would be carried by the centrifugal force resulting from his rotation, cannot be reconciled with the regularity with which the spots frequently re-appear on the eastern limb of the sun. Dr Wilson, having observed that the spots situated near the edge of the disk are narrow, and without a penumbra on the side next the centre, and that only the central spots are completely surrounded by a penumbra (appearances which would be exactly represented by a conical gulf or cavity presented to us under different aspects by the revolution of the sun), was led to adopt the opinion, that the appearances of the spots are occasioned by real excavations in the solar globe. He supposed the sun to consist of a dark nucleus, covered only to a certain depth by a luminous matter, not fluid, through which openings are occasionally made by volcanic or other energies, permitting the solid nucleus of the sun to be seen; and that the umbra which surrounds the spot is occasioned by a partial admission of the light upon the shelving sides of the precipice opposite to the observer. It is evident that, in proportion as these excavations are seen obliquely, their apparent dimensions will be diminished; one of the edges will disappear as it approaches the sun's limb, or come more into view as it advances towards the middle of the disk; when the spot is about to leave the disk, the bottom of the excavation, or the nucleus seen through it, will first disappear, but a sort of faint or obscure spot will remain visible as long as the visual ray penetrates the cavity. These appearances are all conformable to the laws of perspective; but Dr Wilson, wishing to give a still more palpable demonstration of the accuracy of his theory, fitted up a large globe, into which holes of the proper dimensions were inserted; and this machine being placed at a distance, and made to revolve, was found, when examined through a telescope, to exhibit in the course of its revolution all the phenomena of the solar spots.

Theoretical Astronomy. Dr Wilson's theory was keenly combated by Lalande, who adduced several observations of his own, and some by Cassini, that could not be explained by means of it; and urged with reason, that an hypothesis, founded on the uniformity of appearances which in reality are exceedingly variable, was entitled to little consideration. Lalande himself supposed the spots to be scoræ which have settled or fixed themselves on the summits of the solar mountains; an opinion which he grounded on this circumstance, that some large spots which had disappeared for several years were observed to form themselves again at the identical points at which they had vanished.

Herschel's observations. The late Sir William Herschel, with a view to ascertain more accurately the nature of the sun, made frequent observations upon it from the year 1779 to the year 1794. He imagined the dark spots on the sun to be mountains, which, considering the great attraction exerted by the sun upon bodies placed at its surface, and the slow revolution it has upon its axis, he thought might be more than 300 miles high, and yet stand very firmly. He says that in August 1792 he examined the sun with several powers from 90 to 500, when it evidently appeared that the dark spots are the opaque ground or body of the sun, and that the luminous part is an atmosphere, through which, when interrupted or broken, we obtain a view of the sun itself. Hence he concluded that the sun has a very extensive atmosphere, consisting of elastic fluids that are more or less lucid and transparent, and of which the lucid ones furnish us with light. This atmosphere, he thought, cannot be less than 1843, nor more than 2765 miles in height; and he supposed that the density of the luminous solar clouds needs not be much more than that of our aurora borealis, in order to produce the effects with which we are acquainted. The sun, then, if this hypothesis be admitted, is similar to the other globes of the solar system with regard to its solidity, its atmosphere, its surface diversified with mountains and valleys, its rotation on its axis, and the fall of heavy bodies on its surface; it therefore appears to be a very eminent, large, and lucid planet, the primary one in our system, disseminating its light and heat to all the bodies with which it is connected.

Herschel supposed that there are two regions or strata of solar clouds; that the inferior stratum is opaque, and probably not unlike our own atmosphere, while the superior is the repository of light, which it darts forth in vast quantities in all directions. The inferior clouds act as a curtain to screen the body of the sun from the intense brilliancy and heat of the superior regions, and, by reflecting back nearly one half of the rays which they receive from the luminous clouds, contribute also greatly to increase the quantity of light which the latter send forth into space, and thereby perform an important function in the economy of the solar system. The luminous clouds prevent us in general from seeing the solid nucleus of the sun; but in order to account for the spots, he supposes an empyreal elastic gas to be constantly forming at the surface, which, carried upwards by reason of its inferior density, forces its way through the planetary or lower clouds, and mixing itself with the gases which have their residence in the superior stratum, causes decompositions of the luminous matter, and gives rise to those appearances which he describes under the name of *corrugations*. Through the openings made by this accidental removal of the luminous clouds, the solid body of the sun becomes visible, which, not being lucid, gives the appearance of the dark spots or nuclei seen through the telescope. The length of the time during which the spots continue visible renders it evident that the luminous mat-

ter of the sun cannot be of a liquid or gaseous nature; for, in either case, the vacuity made by its accidental removal would instantly be filled up, and the uniformity of appearance invariably maintained. Herschel supposed the luminous clouds to be phosphorescent.

It would be a needless waste of time to enter into any discussion of a theory so entirely vague and fanciful, and so destitute of all solid foundation. Till we are better acquainted with the nature of light, fire, and heat, and have attained to the knowledge of every possible mode in which these elements can be produced and propagated, all hypotheses respecting the construction of the sun can only be gratuitous and conjectural. Some interesting questions, however, arise out of this subject. Whether the inferior stratum of solar clouds is sufficiently dense, as Herschel imagined, to protect the body of the sun from the scorching effects of the surrounding regions of light and heat, and render it a fit habitation for human beings, is a question of no importance to man, or to any thing pertaining to his planet; but it is interesting for him to know whether the light and heat dispensed by the sun are liable to any variation or secular diminution, either connected with the spots, or resulting from a decrease of the sun's volume.

Those philosophers who adopt the hypothesis of the production of light and heat by the vibrations of an ethereal fluid, consider the mass of the sun to be invariable. Those, on the contrary, who attribute these effects to an emanation from the sun, think his mass and volume must be diminished by the incessant discharge of torrents of luminous particles from his surface. During the two thousand years which have elapsed since the first astronomical observations, no diminution of the sun's volume has been perceived; but it must be remarked that such an effect may have taken place, though not yet sensible to our instruments. The sun's diameter is nearly 2000"; and at the distance of 95,000,000 miles a second corresponds to 460 miles. Now, supposing the solar diameter to suffer a daily diminution of two feet, which may be considered as enormous, considering the vast magnitude of the sun, and the excessive rarity of light, the diminution would amount to 800 feet in a year, and to 460 miles, or 1", in 3000 years. Thus, after thirty centuries, the diminution would still be imperceptible, inasmuch as our instruments are not sufficiently accurate to enable us to appreciate, in an observation of this sort, so small a variation as one second.

Some astronomers, after Herschel, have imagined that the existence of the solar spots has an influence on the temperature of the seasons. In 1823 the summer was cold and wet; the thermometer at Paris rose only to 23° of Reaumur, and the sun exhibited no spots; whereas in the summer of 1807 the heat was excessive, and the spots of vast magnitude. The relation, however, between the temperature and the appearance of the solar spots is not so uniform as to give much weight to this opinion. Warm summers, and winters of excessive rigour, have happened in the presence or absence of the spots. The year 1783 was remarkable for its fertility and the magnitude of the solar spots; a dry fog enveloped the greater part of Europe, and was followed by the earthquake of Calabria. Another opinion entertained by Herschel was, that one hemisphere of the sun emits less light than the other, so that when viewed at a great distance he will resemble some stars of which the brilliancy is subject to periodical variations.

By reason of the globular figure of the sun, his surface towards the border of the disk is seen obliquely, and therefore a much greater portion of it is comprehended

Astronomy.

ed under a given visual angle, than when the ray proceeds from his centre. Now, as every point of the sun's surface is supposed to emit an equal quantity of light in all directions, it follows that the light ought to be much more intense near the circumference of the disk, because a greater number of rays will proceed from the larger surface, which forms the oblique base of the luminous cone. Bouguer, deceived by some imperfect experiments, thought the light more intense at the centre of the disk than towards the limb; a circumstance which could only be explained by supposing the light to be diminished by some cause which acts most powerfully with regard to the borders of the disk. Such would be the effect of a dense atmosphere surrounding the sun; for in this case the rays which proceed from the border must traverse a much greater extent of the solar atmosphere, and consequently be absorbed in greater proportion than those which proceed from the central parts and traverse it directly; just as the atmosphere of the earth renders the light of the stars at the horizon much feebler than at the zenith. It has been found, however, that Bouguer's experiments were inaccurate, and that the light is equally intense at the border and the centre. The existence of a solar atmosphere cannot therefore be demonstrated in this manner; but it is clearly indicated by the faint light which is observable round the sun's limb during a total eclipse.

Zodiacal
light.

Another very curious phenomenon connected with the sun, is the faint nebulous aurora which accompanies him, known by the name of the *Zodiacal Light*. This phenomenon was first observed by Kepler, who described its appearance with sufficient accuracy, and supposed it to be the atmosphere of the sun. Dominic Cassini, however, to whom its discovery has been generally but erroneously attributed, was the first who observed it attentively, and gave it the name which it now bears. It is visible immediately before sunrise, or after sunset, in the place where the sun is about to appear, or has just quitted, in the horizon. In total eclipses it is seen surrounding the sun's disk, and resembling the beard of a comet. It has a flat lenticular form, and is placed obliquely on the horizon, as represented in fig. 41, the apex extending to a great distance in the heavens. Its direction is always in the plane of the sun's equator, and for this reason it is scarcely visible in our latitudes, excepting at particular seasons, when that plane is nearly perpendicular to the horizon. When its inclination is great, it is either concealed altogether under the horizon, or at least rises so little above it, that its splendour is effaced by the atmosphere of the earth. The most favourable time for observing it is about the beginning of March, or towards the vernal equinox. The line of the equinoxes is then situated in the horizon, and the arc of the ecliptic SS' (fig. 42) is more elevated than the equator SEQ by an angle of $23\frac{1}{2}$ degrees; so that the solar equator, which is slightly inclined to the ecliptic, approaches nearer to the perpendicular to the horizon, and the pyramid of the zodiacal light is consequently directed to a point nearer the zenith, than at any other season of the year. For example, at the summer solstice, $S''T$, a tangent to the ecliptic, is parallel to EQ the tangent to the equator, and the luminous pyramid is in a plane less elevated by $23^{\circ}\frac{1}{2}$ than at the time of the vernal equinox.

Different
opinions
regarding
the zodiacal
light.

Numerous opinions have been entertained respecting the nature and cause of this singular phenomenon. Cassini thought it might be occasioned by the confused light of an innumerable multitude of little planets circulating round the sun, in the same manner as the milky way owes its appearance to the light of agglomerated myriads of stars. Its resemblance to the tails of comets has been

noticed by Cassini, Fatio Duillier, and others; and Euler endeavoured to prove that they are both owing to similar causes. Mairan, like Kepler, ascribed it to the atmosphere of the sun; and this hypothesis was generally adopted, till it was shown by Laplace to be untenable for the following reasons. The atmosphere of any planet, endowed with a motion of rotation, cannot extend to an indefinite distance: it can only reach to such a height that the centrifugal force is exactly balanced by the force of gravity. Beyond this height the atmosphere would be dissipated by the superior energy of the centrifugal force. Now the height above the sun at which the two forces are equal is that at which a planet, if placed there, would revolve about the sun in the same time in which the sun performs a revolution on his axis. But the orbit of such a planet would be greatly inferior to the orbit of Mercury; for the time in which Mercury makes a revolution in his orbit is eighty-eight days, while the sun revolves about his axis in twenty-five; it is therefore certain that the atmosphere of the sun cannot extend to the orbit of Mercury. Now, the greatest elongation of Mercury does not exceed 28° , and the zodiacal light has been observed to extend to above 100° , reckoning from the sun to the apex of the luminous pyramid. Hence the phenomenon cannot proceed from the sun's atmosphere. Laplace further remarks, that the ratio of the equatorial and polar axes of the solar atmospherical spheroid cannot exceed that of three to two; whence its form would not correspond with the lenticular appearance of the zodiacal light. But to whatever cause this luminous matter is to be attributed, it is certain that it is of extreme rarity, inasmuch as it does not intercept the light of the smallest stars which are seen through it without any diminution of splendour.

On the subject of the solar spots and zodiacal light the following works may be consulted:—Galileo, *Istoria e Dimostrazioni intorno alle Macchie Solari*, Rome, 1613; Scheiner, *Rosa Ursina*, Bracciani, 1630; Hevelius, *Selesographia*, Gedani, 1647; Reutschius, *De Maculis et Fasciis Solaribus*, Wittemb. 1661, 4to; Cassini, *Nouv. CHAP. III.

OF THE MOON.

Next to the sun, the moon is to mankind the most important and interesting of all the celestial bodies. Her conspicuous appearance in the heavens, the variety of her phases, and the rapidity with which she changes her place among the fixed stars, have rendered her at all times an object of admiration to the vulgar; while her proximity to the earth, her physical effects on the ocean, the intricacy of the theory of her motions, and the vast importance of that theory to navigation and geography, have equally

Theoret.
Astronomy.

Theoretical Astronomy. Theoretical claimed the attention of the observer and mathematician; nor is there any other department of astronomy in which their researches have been crowned with more triumphant success, or been rewarded with more brilliant discoveries.

SECT. I.—Of the Phases, Parallax, and Magnitude of the Moon.

The different appearances or phases of the moon were probably the first celestial phenomena observed with any degree of attention. When the moon, after having been for some days invisible, is again seen on the eastern side of the sun, and at a distance of 20 or 30 degrees from him, she appears as a curved thread of silvery light; and her form is that of a crescent, the horns of which are turned towards the east. The breadth of the crescent increases continually in proportion as she separates herself from the sun, till, having obtained a distance of 90°, she appears under the form of a semicircle. At this point she is said to be in her *first quarter*. Continuing her motion to the eastward, the line which terminates the eastern side of her disk assumes the curvature of an elliptic arc, and her visible portion continues to increase till she has attained the distance of 180° from the sun, when she appears perfectly round. She is then *full*, and is said to be in *opposition*, rising as the sun sets, and consoling us by her pale light for the absence of the great luminary. Having passed this point, she begins to approach the sun; her western side now takes the form of the elliptic arc, and her luminous portion diminishes exactly in the same proportion as it increased through the first half of her orbit. About seven days after the full she again appears as a semicircle, the diameter of which is turned towards the west, and she is now at her *third quarter*, and at a distance of 90° from the sun. The semicircle after this changes into a crescent, and she continues to approach the sun, till, having advanced to within 20° or 30° from him, she again disappears, being lost in the splendour of his rays. These phases regularly succeed each other, and the time in which they run through all their changes is about 29½ days. When the moon passes the meridian at the same time with the sun, she is said to be in *Conjunction*. The two points of her orbit in which she is situated when in opposition or conjunction are called the *Syzygies*; those which are 90° distant from the sun are called the *Quadratures*; and the intermediate points between the syzygies and quadratures are called the *Octants*.

A slight attention to the lunar phases during a single revolution will be sufficient to prove that they are occasioned by the reflection of the sun's light from the opaque spherical surface of the moon. This fact, which was recognised in the earliest ages, will be made obvious by the help of a diagram. If the moon is an opaque body we can only see that portion of her enlightened side which is towards the earth. Therefore, when she arrives at that point of her orbit A (fig. 43) where she is in conjunction with the sun S, her dark half is towards the earth, and she disappears, as at *a*, there being no light on that half to render it visible. When she comes to her first octant, at B, or has gone an eighth part of her orbit from her conjunction, a quarter of her enlightened side is towards the earth, and she appears horned, as at *b*. When she has gone a quarter of her orbit from her conjunction, to C, she shows us one half of her enlightened side, as at *c*, and we say she is a quarter old. At D she is in her second octant, and by showing us more of her enlightened side she appears gibbous, as at *d*. At E her whole enlightened side is towards the earth, and therefore she appears round, as at *e*, when we say it is full moon. In her third octant, at F, part of her dark side being towards the earth,

she again appears gibbous, and is on the decrease, as at *f*. At G we see just one half of her enlightened side, and she appears as a semicircle, as at *g*. At H we only see a quarter of her enlightened side, being in her fourth octant, when she appears horned, as at *h*. And at A, having completed her course from the sun to the sun again, she disappears, and we say it is new moon. Thus, in going from A to E, the moon seems continually to increase; and in going from E to A, to decrease in the same proportion, exhibiting like phases at equal distances from A and E.

The magnitude of the visible portion of the moon's disk thus depends on the situation of the moon relatively to the sun and the earth, and is easily determined geometrically from her elongation or angular distance from the sun. Let ADBC (fig. 44) be the projection of the lunar orb on the plane which passes through the centres of the sun, moon, and earth; let S be the place of the sun, E that of the earth, M the centre of the projection, and AB, CD two diameters perpendicular to SM and EM respectively, and let EM meet the circumference in G. It is evident that AGDB represents the hemisphere illuminated by the sun, and CAGD that which is visible from the earth; the whole portion of the visible disk, therefore, is represented by AGD, or by AG and DG. Now, if we conceive the moon's surface to be projected on the plane which passes through her centre perpendicular to the visual ray, the illuminated portion of the disk DG will appear as a semicircle, while the part GA will appear as a semi-ellipse, the minor axis of which is to its major as MF to MC, AF being perpendicular to MC. The eye at E will therefore see the semicircle DMG, together with the semi-ellipse GMA, and the visible part will be to the entire disk as DF : DC, that is, as $1 + \sin. \phi$: 2, or, as $1 + \cos. \phi$: 2; ϕ being equal to EMS the elongation of the earth from the sun as seen from the moon. The geocentric elongation of the moon from the sun, or the angle MES = ψ , may be substituted instead of ϕ , when we know the ratio of the distances ES = r and MS = R; for $\sin. \phi = \frac{r}{R} \sin. \psi$, whence $\cos. \phi =$

$\sqrt{1 - \frac{r^2}{R^2} \sin.^2 \psi}$, and the above proportion becomes

$$DF : DC :: 1 + \sqrt{1 - \frac{r^2}{R^2} \sin.^2 \psi} : 2.$$

When the moon is in opposition the angle $\phi = 0$, whence $1 + \cos. \phi = 2$, and the whole disk is visible. At the conjunction $\phi = 180^\circ$, and $1 + \cos. \phi = 0$; the moon is consequently invisible.

The triangle EMS likewise furnishes the means of finding the distance of the moon when that of the sun is known; or reciprocally, the distance of the sun from that of the moon: but for this purpose it is necessary to observe accurately the limit of illumination, which is not easily done. Let ADBE (fig. 45) be the illuminated part of the moon ACBE. The distance between the cusps A and B, measured by the micrometer, gives the major axis of the ellipse ADB, and the semiconjugate axis DM is found by measuring in the same manner the distance ED, and subtracting EM, half the transverse AB. This gives $\frac{DM}{AM} = \cos. EMS$ (fig. 44); this gives the angle EMS or M; and from SEM, which is given by observation, we have ESM or S = $180^\circ - E - M$; whence M and S are given angles; and from the property of the triangle we have $EM = ES \frac{\sin. S}{\sin. M}$, or $ES = EM \frac{\sin. M}{\sin. S}$. The calculation would be greatly facilitated if the observation

Theoretical
Astronomy.

were made at the exact instant when the moon is dichotomized, or in her first or third quarter, for the elliptic arc then becomes a straight line and the angle $EMS = 90^\circ$; so that $\sin. M = 1$. In this case therefore we have $EM = ES$

$\sin. S = ES \cos. E$, and $ES = \frac{EM}{\cos. E}$, which gives the

ratio of the distances of the sun and moon. In this manner Aristarchus of Samos attempted to compare the distance of the two luminaries; and although his result was extremely erroneous, inasmuch as he found the distance of the sun to be only between eighteen and twenty times greater than that of the moon, whereas it is actually 380 times greater, yet the idea was an ingenious one, and the method perfectly accurate in theory. The error arose from the inaccuracy of the ancient instruments, and the impossibility of observing to within a few minutes the exact time of the dichotomy. Besides, as the angle at the sun is extremely small, a very slight error either with regard to the time or the angle has a great influence on the result.

Parallax of
the moon.

The moon's absolute distance from the earth is obtained by means of her parallax, which, on account of her proximity, is very considerable, and can therefore be determined by the methods which were explained in chap. i. sect. 2. On comparing her parallaxes observed at different times, they are found to differ considerably in value. Thus, according to Lalande, the greatest horizontal parallax at Paris is $61' 29''$, the smallest $53' 51''$; and it assumes every possible value between these two extremes. The horizontal parallax being the angle which the earth's radius subtends at the moon, and consequently equal to the radius of the earth divided by the moon's distance, the perigean and apogean distances corresponding to the extreme parallaxes are respectively 55·916 and 63·842 semidiameters of the earth. The ratio of these two numbers, or of the extreme values of the parallax, is 1·1417, and denotes the greatest variations of the moon's distance from the earth. The ratio of the corresponding quantities in the case of the sun is only 1·034; hence the moon's distance is subject to much greater variations than that of the sun.

These differences in the value of the parallax arise from the variations of the moon's distance from the earth; but it is also observed to differ sensibly at different points of the earth's surface, even at the same instant of time. If the earth were spherical, the horizontal parallax of the moon, supposing her distance to be invariable, would be the same at whatever part of the earth it might be observed. The case is, however, different; for, on account of the spheroidal figure of the earth, the section made by every vertical plane gives a different ellipse, no one of which even passes through the centre of the earth, excepting indeed the cases in which the place of the observer is on the equator or under the pole; for in all other cases the perpendicular to the surface of the earth does not pass through its centre. Hence it is necessary, in speaking of the horizontal parallax, to specify the place of the observation.

Since the parallax of the moon is subject to incessant variation, it is necessary to assume a certain mean value of it, about which the true and apparent values may be conceived to oscillate. This is denominated the *constant* parallax. It is evident that it cannot be found by taking the arithmetical mean of the extreme values; for by reason of the disturbing force of the sun, the eccentricity of the lunar orbit, and consequently the perigean and apogean distances, are constantly varying; and as the quantity by which one of these distances is increased is not equal to that by which the other is diminished, it follows

that the mean of the perigean and apogean parallaxes will not be a constant quantity, but different in successive revolutions of the moon. If we abstract from all the inequalities of the lunar orbit, and suppose the moon to be at her mean distance and mean place, the constant parallax will be the angle under which a given semidiameter of the earth is seen by a spectator at the moon in such circumstances. According to Lalande, the following are the values of the constant parallax:—

Under the equator.....	57' 5"
Under the pole.....	56 53·2
For the latitude of Paris.....	56 58·3
For the radius of a sphere equal in volume to the earth.....	57 1

The mean equatorial parallax being $57' 5''$, its double is $1^\circ 54' 10''$, which expresses the angle subtended by the diameter of the earth at the distance of the moon. The angle subtended by the moon at the same distance is $31' 26''$; whence the diameter of the moon is to that of the earth as $31' 26''$ is to $1^\circ 54' 10''$; that is, as 524 to 1899, or as 3 to 11 nearly. According to the tables of Burg, the accurate expression of the above ratio is $1 : 0.27293$; hence the true diameter of the moon is 0.27293 diameters of the terrestrial equator. The surface of the moon is consequently $(0.27293)^2 = 0.0744908 = \frac{1}{13.4243}$ of that of the earth, and its volume $(0.27293)^3 = 0.0203308 = \frac{1}{49.1863}$, or, in round numbers, $\frac{1}{50}$ th of the volume of the earth.

SECT. II.—Of the Elements of the Lunar Orbit.

1. *Nodes and Inclination of the Lunar Orbit.*—A few simple observations of the right ascensions and declinations of the moon suffice to show that her path is confined nearly to a plane, having only a small inclination to the plane of the ecliptic. If her path were rigorously confined to this plane, a single revolution would be sufficient to determine its inclination; but as numerous disturbing causes exist, which produce inequalities in all the elements of the lunar motion, it is only by taking the mean value of a great number of observations that these elements can be astronomically determined. In fixing the position of the plane of the orbit, the first object is to determine the straight line formed by its intersection with the plane of the ecliptic; that is to say, to determine the line of the *Nodes*. This would be at once accomplished if it were possible to observe the instant at which the moon's latitude is nothing; for at this instant her centre is in the plane of the ecliptic, and consequently her longitude is the same as the longitude of the node. But as the accuracy of modern practice requires that all important observations be made in the plane of the meridian, and as it could only happen by a very rare coincidence that the latitude deduced from the meridional right ascensions and declinations would be exactly zero, it is necessary to have recourse to a process of calculation to find the precise place of the node.

Let LNL' (fig. 46) be a portion of the ecliptic, MNM' Fig. 46 of the lunar orbit, N the place of the node, and $ML = l$, $ML' = l'$ be two latitudes on opposite sides of the ecliptic. The two right-angled triangles give, according to Napier's Rules,

$$\tan. N = \frac{\tan. l}{\sin. NM} = \frac{\tan. l'}{\sin. NM'};$$

therefore,

$$\frac{\sin. NM}{\sin. NM'} = \frac{\tan. l}{\tan. l'};$$

whence,

$$\frac{\sin. NM - \sin. NM'}{\sin. NM + \sin. NM'} = \frac{\tan. l - \tan. l'}{\tan. l + \tan. l'};$$

Theoretical
Astronomy.

Theoretical
Astronomy.

that is, by the trigonometrical formulæ,

$$\frac{\tan. \frac{1}{2}(NM - NM')}{\tan. \frac{1}{2}(NM + NM')} = \frac{\sin. (l - l')}{\sin. (l + l')},$$

$$\text{or } \tan. \frac{1}{2}(NM - NM') = \tan. \frac{1}{2}MM' \cdot \frac{\sin. (l - l')}{\sin. (l + l')}.$$

Having therefore obtained an expression for the difference of NM and NM' , and knowing also their sum MM' , which is the difference of the longitudes of the moon at the time of the two observations, it is easy to deduce NM or NM' ; consequently the longitude of the node is determined.

The *Ascending Node* of the lunar orbit is that point of the ecliptic through which the moon passes when she rises above the ecliptic towards the north pole: it is distinguished by the character Ω . The *Descending Node*, $\oslash$, is the opposite point of the ecliptic, through which she passes when she descends below that plane towards the south pole. The nodes of the lunar orbit were anciently called the head and tail of the Dragon.

The position of the nodes is not fixed in the heavens. They move in a retrograde direction, or contrary to the order of the signs; and their motion is so rapid that its effects become very apparent after one or two revolutions. Regulus, a star of the first magnitude, is sometimes eclipsed by the moon; and as the latitude of this star is only about $27'$ or $28'$, it is certain that when that phenomenon occurs the moon is very near her node. Suppose it to be the ascending node: the month following it will be observed that the moon passes to the north of Regulus; and every succeeding month she will pass farther to the north of the same star, till at the end of four or five years, when her meridional altitude will be about 5° greater than that of Regulus. Having attained this elevation, her latitude begins to diminish; and, after a period of about nine years, Regulus is again eclipsed by the moon in her descent to the southern side of the ecliptic. The moon after this passes to the south of the star for the following nine years; and at the end of $18\frac{1}{2}$ years the nodes have returned to their first position, after accomplishing a complete revolution. The same result is found from the observation of eclipses, the magnitude of which depends on the moon's latitude; and therefore, if the nodes remained fixed, the eclipses would always be of the same magnitude in the same quarter of the heavens. This, however, is not the case; and it is only after about $18\frac{1}{2}$ years that they begin to return in the same order.

The mean retrograde motion of the nodes is found by the comparison of observations made at distant epochs to amount to $19^\circ 19' 42'' \cdot 316$ in a mean solar year, and the time in which they make a complete revolution is consequently 6798 days, 4 hours, 17 min. 43.18 sec. The longitude of the ascending node on the 1st of January 1801 was $13^\circ 53' 17'' \cdot 7$; hence its position at any other epoch is easily deduced, since we know the rate of its mean motion.

The inclination of the lunar orbit may be determined either by observing the moon's greatest latitudes, or it may be computed from the formula $\tan. N = \frac{\tan. l}{\sin. NM}$, when

her latitude and distance from the node are known. The angle N , or the inclination, is observed to vary between 5° and $5^\circ 17' 35''$. The mean inclination may therefore be taken at $5^\circ 8' 48''$.

The retrograde motion of the moon's nodes, as well as all the other inequalities of the lunar motion, is occasioned by the attracting power of the sun, which varies in intensity with the sun's longitude, or distance from his perigee. The principal inequality to which the inclination of the lunar orbit is subject, is proportional to the cosine

of double the sun's distance from the moon's ascending node. In fact, the sun and earth being always in the plane of the ecliptic, when the moon is also in that plane the action of the sun will have no tendency to increase or diminish her latitude; it will only affect her radius vector, or distance from the earth. But if the moon is not in the plane of the ecliptic, the sun's attracting force will not only affect her distance from the earth, but also tend to bring her nearer to the ecliptic; and this action will be greater in proportion to her deviation from that plane. When the nodes are in the quarters, and the limits of latitude in the syzygies, the inclination is 5° , as was found by Ptolemy; but when the nodes are in the syzygies, and the limits in the quarters, the inclination is $5^\circ 17' 35''$. It has therefore a mean value of $5^\circ 8' 48''$, when the nodes and limits coincide with the octants. Denoting therefore the greatest deviation from the mean values by x , this deviation will pass through all its values between $+x$ and $-x$ while the sun's distance from the ascending node varies from 0° to 90° . It may therefore be represented by a function which varies as the cosine of twice that distance, for the cosine of an angle runs through all its changes from $+1$ to -1 between 0 and 180° . Hence the equation which expresses the principal inequality of the moon's latitude is

$$(8' 48'') \cos. 2 \odot \text{'s distance from } \Omega \text{'s } \Omega.$$

The co-efficient $8' 48''$ is called, in astronomy, the *Co-efficient of the Argument*, the argument itself being the function by which the inequality is represented.

This periodic inequality of the moon's latitude was discovered by Tycho Brahe, from a comparison of the greatest latitudes at different epochs with the corresponding positions of the moon with reference to her nodes. He observed that these latitudes oscillate about the mean value of $5^\circ 8' 48''$; and as the greatest latitudes give immediately the inclination of the moon's orbit to the plane of the ecliptic, it necessarily followed that the inclination is subject to similar variations. The motion of the node of the lunar orbit is also subject to an inequality, depending on the same angle as the preceding, but proportional to its sine. Tycho explained these two inequalities by a very simple hypothesis, similar to that by which we have explained the oscillations of the terrestrial equator, namely, a slight nutation of the earth's axis. In the present case it is only necessary to place the mean pole of the lunar orbit at the distance of $5^\circ 8' 48''$ from the pole of the ecliptic, and to suppose the true pole to describe a small ellipse about the mean pole in the same time that the sun occupies in making a semi-revolution with regard to the nodes of the moon's orbit, that is, in 173.309 days.

There are various other inequalities which affect the latitude of the moon and the inclination of her orbit, to correct which, no fewer than twelve equations are given in the recent and most accurate tables. The greater part of them are, however, only known from theory, and are so small that even their accumulated effects are scarcely perceptible to observation.

The inclination of the lunar orbit to the plane of the terrestrial equator occasions considerable differences in the intervals between the moon's rising or setting on successive days, and gives rise to the phenomenon of the *Harvest Moon*. As the daily motion of the moon is about 13 degrees from west to east, it follows that if she moved in a plane parallel to the equator, she would rise 50 minutes later every successive evening, because her orbit would then make the same angle with the horizon at all seasons of the year, and the intervals between her consecutive risings would be constant. For the sake of explanation, we may here suppose the moon to move in the plane of

Phenomenon of the harvest-moon.

Theoretical Astronomy. the ecliptic. Now, the time in which a given arc of the ecliptic rises above the horizon depends on its inclination to the horizon. In our latitudes the inclination of the ecliptic at different points to the horizon varies so much, that at the first point of Aries an arc of 13° becomes visible in the short space of 17 minutes, while at the 23d of Leo the same arc will only rise above the horizon in one hour and 17 minutes. Hence, when the moon is near the first point of Aries, the difference of the times of her rising on two successive evenings will be only about 17 minutes; and as this happens in the course of every revolution, she will rise for two or three nights every month at nearly the same hour. But the rising of the moon is a phenomenon which attracts no attention, excepting about the time when she is full, that is, when she rises at sunset. In this case she is in opposition to the sun, and consequently, if she is in Aries, the sun must be in Libra, which happens during the autumnal months. At this season of the year, therefore, the moon, when near the full, rises for some evenings at nearly the same hour. This circumstance affords important advantages to the husbandman, on which account the phenomenon attracts particular attention.

It is obvious, that as this phenomenon is occasioned by the oblique position of the lunar orbit with regard to the equator, the effect will be greater than what has just been described if the plane of that orbit makes a greater angle with the equator than the plane of the ecliptic does. But we have seen that the plane of the moon's orbit is inclined to the ecliptic in an angle exceeding 5° ; consequently, when her ascending node is in Aries, the angle which her orbit makes with the horizon will be 5° less than that which the ecliptic makes with the horizon; and the difference of time between her risings on two successive evenings will be less than 17 minutes, as would have been the case had her orbit coincided with the ecliptic. On the contrary, when the descending node comes to Aries, the angle which her orbit makes with the horizon will be greater by 5° , and consequently the difference of the times of her successive risings will be greater than if she moved in the plane of the ecliptic. If when the full moon is in Pisces or Aries the ascending node of her orbit is also in one of those signs, the difference of the times of her rising will not exceed one hour and forty minutes during a whole week; but when her nodes are differently situated, the difference in the time of her rising in the same signs may amount to $3\frac{1}{2}$ hours in the space of a week. In the former case the harvest-moons are the most beneficial, in the latter the least beneficial, to the husbandman. All the variations in the intervals between the consecutive risings or settings take place within the period in which the line of the nodes makes a complete revolution.

2. *Dimensions, Eccentricity, and Apsides of the Lunar Orbit; and the Inequalities of the Moon's motion.*—Since the moon moves in a plane orbit, the projection of her path on the surface of the celestial sphere will be a great circle. But the variations observable in the magnitude of her apparent diameter, and in the velocity of her motion, prove that if her orbit is a circle, the earth is at least not placed at its centre. The numerous perturbing causes which affect her motion render the exact determination of her orbit a matter of great difficulty; but observation shows that it deviates very little from an ellipse, of which the centre of the earth occupies one of the foci. It has also been found that the spaces passed over by the radius vector of the moon are very nearly proportional to the times of description; which is the distinctive character of the elliptic motion.

Theoretical Astronomy. In order to obtain a correct idea of the figure and position of the orbit, it is necessary to know its major axis, its eccentricity, and the position of its apsides. The major axis is equal to the sum of the greatest and least distances, and these have already been stated to be respectively 63·842 and 55·916 semidiameters of the earth; whence, supposing the earth's radius to be 4000 miles, the major axis of the lunar orbit will amount in round numbers to 480,000 miles. It may be here remarked that the moon's distance is an element which may be practically determined with great exactness. A variation of $1''$ in the parallax would occasion an error of only about 67 miles in the determination of the distance; therefore, since the parallax is certainly known to within $4''$, the greatest error in the distance deduced from it cannot exceed 280 miles out of about 240,000 miles.

An approximation to the eccentricity of the orbit of the moon is easily obtained from the variations of her apparent diameter. The moon's apparent diameter is observed to vary between $29' 30''$ and $33' 30''$ very nearly. Now, let D denote the mean, D' the apogean, D'' the perigean diameter, and e the eccentricity. We shall then have

$$D' = \frac{D}{1+e} = 29' 30''$$

$$D'' = \frac{D}{1-e} = 33' 30'',$$

$$\frac{D'}{D''} = \frac{1-e}{1+e} = \frac{29' 30''}{33' 30''};$$

whence we deduce

$$e = \frac{33' 30'' - 29' 30''}{33' 30'' + 29' 30''} = \frac{4'}{63'} = 0.0635.$$

This eccentricity corresponds to an equation of the centre amounting to $7^\circ 16'$, and is much more considerable than that of the solar orbit, which, as we have before seen, amounts only to $0^\circ 01' 68''$. The result just given is, however, only to be considered as approximative, and is, in fact, considerably too large. In the best and most recent tables the value assigned to the eccentricity of the lunar orbit is 0.0548442, and the corresponding equation of the centre $6^\circ 17' 12''.7$. (See *Astronomical Tables and Formulae*, by Francis Baily, Esq. London, 1827.)

The place of the apsides is likewise found from observations of the moon's apparent diameter, because at these points of the orbit the apparent magnitude has its maximum and minimum values. But as the apparent magnitude varies very slowly at the apsides, it is preferable, as Lalande remarks, to choose the points of mean distance where its variations are most rapid. Having selected two observations which give the same apparent diameter at two opposite points of the orbit, we shall have two points evidently at equal distances from the perigee, the longitude of which will therefore be given at the middle time between the two observations. In comparing the positions of the apsides thus determined at different epochs, it is found that they have a rapid progressive motion, that is, according to the order of the signs. In Mr Baily's tables the motion of the perigee is stated to be $4069^\circ 04' 62''.78$, or 11 revolutions $+ 109^\circ 2' 46''.6$, in 36525 mean solar days. Its mean motion in a mean solar day is consequently $6' 41''$; and in 365 mean solar days, $40^\circ 39' 46''.36$. Hence the time in which it completes a sidereal revolution is $3232^\circ 57' 53''.43$ mean solar days. The period of a tropical revolution of the apsides is $3231^\circ 47' 51''$ mean solar days = 3231 days, 11 hours, 24 minutes, 0.8 seconds, or nearly 9 years. This mean motion of the lunar apsides is, however, subject to periodic inequalities of considerable magnitude, and therefore can only be determined accurately by means of observations separated from

Theoretical Astronomy. each other by a long interval of time. In the tables just quoted, the epoch is the commencement of the present century, when the longitude of the perigee was in $266^{\circ} 10' 7'' 5$. From this and the rate of the mean motion, the longitude of the perigee at any other epoch may be easily computed.

Inequalities of the lunar orbit. If the moon's place in her orbit were not subject to the influence of any disturbing force, her true longitude, or distance from the apsis, would be found at any instant from the theory of the elliptic motion, supposing her mean motion, or the time of a return to the same perigee or apogee, to be accurately known. Thus, supposing E to denote the maximum elliptic equation, which, as we have already stated, amounts to $6^{\circ} 7' 12'' 7$, we should have the true longitude = mean longitude + $E \sin A$, A being the moon's mean anomaly, and the longitudes counted from the perigee. This first equation or correction of the mean motion results solely from the circumstance that the moon moves in an elliptic orbit, according to the laws of Kepler, in the same manner as the sun and all the planets. Its argument is the mean anomaly A , and its period the anomalistic month. But the moon's longitudes, as determined in this manner, are far from agreeing with observation; and several other corrections must be applied, the accurate determination of which forms the principal object of the lunar theory.

Evection. After the equation of the centre, the most considerable of the inequalities of the moon's longitude is that to which Boulliaud gave the name of the *Evection*. It was noticed by Hipparchus; but it was Ptolemy who discovered its law, and gave a construction which represents its general effects with great accuracy. These effects are to diminish the equation of the centre when the line of the apsidal lies in syzygy, and to augment it when the same line lies in quadratures. Thus, supposing the apsidal to lie in syzygy, and that it is sought to compute the moon's true longitude about seven days after she has left the perigee, by adding the equation of the centre to the mean anomaly, the resulting longitude will be found to be above $80'$ less than that which is given by observation. But if the line of the apsidal lies in quadratures, the place of the moon at about the same distance, that is, 90° from the perigee, computed in the same manner, will be found to be before the observed place by above $80'$; that is, the computed will be *greater* than the observed longitude, by more than 80 minutes. After a long series of observations, astronomers have found that the inequality in question is represented with great exactness, by supposing it proportional to the sine of twice the mean angular distance of the moon from the sun, minus the mean anomaly of the moon. In Baily's tables, its maximum value is stated to be $1^{\circ} 20' 29'' 9$; whence, representing the angular distance of the sun and moon by $\mathcal{D} - \odot$, and the mean anomaly as before by A , the correction due to the evection will be

$$(1^{\circ} 20' 29'' 9) \sin. [2(\mathcal{D} - \odot) - A].$$

Variation. A third inequality of the lunar motion, called the *Variation*, was discovered by Tycho Brahe, who found that the moon's place, calculated from her mean motion, the equation of the centre, and the evection, does not always agree with the true place, and that the variations are greatest in the octants, or when the line of the apsidal makes an angle of 45° with that of the syzygies and quadratures. Having observed the moon at different points of her orbit, he found that this correction has no dependence on the position of the apsidal, but only on the moon's elongation from the sun. Its maximum value is additive in the octants which come immediately *after* the syzygies, where the elongation is 45° , or $180^{\circ} + 45^{\circ}$, and subtractive in the octants which *precede* the syzygies, where the

Theoretical Astronomy. elongation is $360^{\circ} - 45^{\circ}$, and $180^{\circ} - 45^{\circ}$. It vanishes altogether in the syzygies and quadratures where the elongation is 0° , 180° , 90° , or 270° ; and on this account it was not perceived by the ancient astronomers, who only observed the moon in those positions. It will be readily perceived, from the limits between which it varies, that it is proportional to the sine of twice the angular distance between the sun and moon. Its maximum value, or the co-efficient of its argument, is $35' 41'' 9$; hence the correction necessary on account of it is represented by the formula

$$(35' 41'' 9) \sin. 2(\mathcal{D} - \odot).$$

When this equation is added to the two preceding **Annual equation.** ones, the differences between the computed and observed places of the moon are brought within narrower limits; but they do not yet disappear altogether except in the months of June and December, and about the time of the equinoxes they are found to amount to eleven or twelve minutes. This inequality was observed by Tycho and Kepler, though neither of them determined its magnitude. They supposed it to be an equation of time peculiar to the moon; and under this form Horrox inserted it in his tables, assigning its maximum value at $11' 16''$, which differs only by four seconds from that which is obtained from the most accurate modern observations. On account that it is regulated by the seasons, and depends not on the lunar orbit, but the anomaly of the sun, Kepler gave it the name of the *Annual Equation*. By reason of this inequality the motion of the moon is slower than the mean motion during the winter months, when the motion of the sun is most rapid; and, on the contrary, is most rapid in summer, when the sun's motion is slowest. Hence its argument is the same as that of the equation of the centre of the sun, but with a contrary sign. It is therefore proportional to the sine of the sun's mean anomaly; its period is the anomalistic year, and its maximum value is found by observation to be $11' 11'' 9$; hence it is expressed by the formula

$$(11' 11'' 9) \sin. \odot's \text{ mean anomaly.}$$

If we now collect these equations we shall obtain the following corrected expression of the moon's true place:

$$\begin{aligned} \mathcal{D}'s \text{ true longitude} &= \mathcal{D}'s \text{ mean longitude,} \\ &+ (6^{\circ} 17' 12'' 7) \sin. A \\ &+ (1^{\circ} 20' 29'' 9) \sin. [2(\mathcal{D} - \odot) - A] \\ &- (35' 41'' 9) \sin. 2(\mathcal{D} - \odot) \\ &- (11' 11'' 9) \sin. \odot's \text{ mean anomaly.} \end{aligned}$$

For the physical cause of the three last-mentioned inequalities, viz. the evection, the variation, and the annual equation, see *Physical Astronomy*, sect. ii. par. 37, 38, and 39. They are the principal but not the only periodic inequalities which affect the longitude of the moon; for the profound investigations of modern science have detected many others, which, by reason of their small values, and the manner in which they are blended with one another, would have eluded all attempts to discover their period or their law by observation alone. Observation can make known only the joint effect of the independent equations, and thereby indicate their existence. In order to separate them and determine their respective values, it is indispensable to have recourse to the physical theory, from which alone the various circumstances of the lunar motion can be properly determined. Newton was the first who attempted to compute *a priori* the inequalities of the moon's motion, and thereby led the way in a research which was prosecuted with infinite ingenuity and profound analytical skill by D'Alembert, Clairaut, Euler, and other illustrious mathematicians of the last century, and which was only brought to a successful termination by the labours of Laplace. The formulæ given in the seventh

Theoretical Astronomy. book of the *Mécanique Céleste*, for a great number of new inequalities derived from the theory of attraction, form the basis of the lunar tables of Burg and Burckhardt. It is to these theoretical researches that we are indebted for the precision with which the moon's motion is actually known, and the great advantages which thence result to geography and navigation. The recent tables contain no fewer than twenty-eight equations of longitude, all which may be regarded as corrections of the mean values of the four which we have explained, and which are themselves corrections of the mean motion. It is thus that astronomy approaches nearer and nearer, by every successive step, to the last term of a series which would represent the orbits and motions of the celestial bodies with absolute accuracy.

Acceleration of the mean motion of the moon. The lunar inequalities which we have as yet considered are all of a periodic nature, are compensated in the course of a comparatively small number of years, and have passed through many complete revolutions since the commencement of the history of astronomical observations. But there are, as in the case of the sun, others of a different kind, the periods of which are so long that, with reference to the duration of human life, they may be considered as permanently affecting the elements of the lunar orbit. These are the *Secular Inequalities*, the most remarkable of which is the acceleration of the moon's mean motion.

On comparing the lunar observations made within the last two centuries with one another, there results a mean secular motion greater than that which is given by comparing them with those made by Ebn-Jounis, near Cairo, towards the end of the 10th century, and greater still than that which is given by comparing them with observations of eclipses made at Babylon in the years 719, 720, and 721 before our era, and preserved by Ptolemy in the *Almagest*. These comparisons, which have been made by different astronomers with the utmost care, prove incontestably the acceleration of the motion of the moon from the Chaldeans to the Arabians, and from the Arabians to the present times.

The acceleration of the moon's mean motion was first remarked by Dr Halley, and mentioned in his *Notes* on the observations of Albategnius, inserted in the *Philosophical Transactions* for 1693. It was fully confirmed by Dunthorne, who was led by the discussion of a great number of ancient observations of eclipses, to suppose that it proceeded uniformly at the rate of $10''$ in a hundred years; a supposition which consequently gave him a correction for the mean longitude of the moon proportional to the square of the time, or of $10''$ multiplied by the square of the number of years elapsed between 1700 and the epoch of the calculation. This was the first attempt to estimate the value of the secular equation, which had hitherto been confounded with the mean secular motion. By a similar discussion of ancient observations, Mayer was likewise led to a secular equation proportional to the square of the time, which, in his first *Lunar Tables*, published in 1753, he valued at $7''$ for the first century, counting from the year 1700, but which he advanced to $9''$ in his last tables, published in 1770. Lalande found it to amount to $9''.886$, and therefore agreed with Dunthorne in estimating the acceleration at $10''$ for the first century after 1700. Delambre subsequently undertook to determine accurately the actual motion of the moon in a century, from a comparison of the best modern observations. He found it to amount to $307^{\circ} 53' 9''$ (rejecting the circumferences), while the most ancient observations agree in making it less by 3 or 4 minutes. The equation, which, in consequence of these comparisons, was empirically introduced into the tables, has been confirmed by

Theoretical Astronomy. the theory of gravitation; and the discovery of the physical cause, and of the law of the acceleration, due to Laplace, forms one of the most brilliant triumphs of modern science. In 1786 Laplace demonstrated that the acceleration is one of the effects of the attraction of the sun, and connected with the variations of the eccentricity of the earth's orbit in such a manner that the moon will continue to be accelerated while the eccentricity diminishes, but that it will disappear when the eccentricity has reached its maximum value; and when that element begins to increase, the mean motion of the moon will be retarded.

In order to take into account the effects of the acceleration in the determination of the mean longitude, M. Damoiseau has given the following formula for the secular variation; $10''.7232 n^2 + 0''.019361 n^3$, where n is the number of centuries from 1801; so that if L is the mean longitude of the moon on the 1st of January 1801, and m is the secular motion at that epoch, the mean longitude will be $L + mn + 10''.7232 n^2 + 0''.019361 n^3$ after n centuries. By means of this equation the tables satisfy the most ancient observations, and may be extended to at least a thousand years from the present epoch. It is only necessary to observe, that, in applying the formula, n must be taken negatively, if the epoch is anterior to 1801.

The same cause which gives rise to the acceleration of the mean motion, namely, the diminution of the eccentricity of the earth's orbit, also occasions secular inequalities in motion of the perigee and nodes of the orbit of the moon. These two inequalities are, however, affected with opposite signs to that of the former; that is, while the mean motion of the moon is accelerated, the motion of her perigee and that of her nodes are retarded. They were deduced by Laplace from theory, and the equations by which they are expressed are connected with one another by a very simple ratio. If we take A to represent the secular acceleration of the mean motion, the secular variation of the perigee found by Laplace is $-4.00052 A$, and that of the nodes $-0.735452 A$. From this Laplace concluded that the three motions of the moon, with respect to the sun, to her perigee, and to her nodes, are accelerated, and that their secular equations are in the ratio of the above numbers. By pushing the approximations to a great length, MM. Plana and Carlini, and M. Damoiseau, in *Memoirs* which obtained the prize of the Academy of Sciences for 1820, have found different numbers; those of Damoiseau are 1, 4.702, and 0.612. These important results of theory are all confirmed by observation.

The three secular inequalities which have been pointed out will obviously occasion others; for all quantities depending on the mean motion, the motion of the perigee, or of the nodes, must be in some degree modified by them. Thus the mean anomaly, which is the difference of the mean longitude of the moon and the mean longitude of the perigee, is subject to a secular equation equal to the difference of the secular equations affecting the longitudes of the moon and the perigee. The radius vector, the eccentricity and inclination of the orbit, are affected by the secular inequality of the mean motion, which, although too minute to have been hitherto appreciable, will acquire sensible values in the course of ages. The major axis of the ellipse is the only element exempted from inequalities of this sort. It is not probable, however, that the utmost efforts of science will ever make us acquainted with all the irregularities to which the moon's motion is subject. They can only be developed by the complete integration of the differential equations of motion; an integration which is laboriously performed term by term, and which, when attempted to be carried beyond a certain point, transcends

Theoretical Astronomy. the limits of human patience and industry. What is most essential is to select, among the multitude of terms, such as may possibly acquire considerable co-efficients by integration.

The following table exhibits in one view the different elements of the lunar orbit. The epoch is the commencement of the present century.

Mean inclination to the plane of the ecliptic.....	5°	8'	47".9
Longitude of ascending node.....	12	53	17.7
Motion of node in 365 mean solar days	19	19	42.316

Mean motion of perigee in 365 mean solar days.....	40	39	45.36
Mean longitude.....	118	17	8.3
Greatest equation of the centre.....	6	17	12.7
Eccentricity.....	0.0548442		
Mean distance from the earth in diameters of the terrestrial equator.....	29.982075		

SECT. III.—Of the different Species of Lunar Months.

In treating of the sun, we took notice of three different species of revolutions or years, namely, the mean solar year, or the interval of time which the sun employs in performing a complete revolution with regard to the equinoxes; the sidereal year, or the time in which he returns to the same fixed star; and the anomalistic year, or the time in which he returns to the same point of his ellipse. In like manner, if we understand by the term *month* the time which the moon employs to make an entire revolution relatively to any given point, movable or fixed, we shall have as many different species of months as there are different motions with which that of the moon can be compared. For example, if we estimate her revolution relatively to the sun, the month will be the time which elapses between two consecutive conjunctions or oppositions. This is called the *synodic month*, *lunar month*, or *lunation*. If we consider her revolution as completed when she has gone through 360° of longitude counted from the movable equinox, we shall have the *tropical* or *periodic month*. The interval between two successive conjunctions with the same fixed star is the *sidereal month*. A revolution with regard to the apsides of her orbit, that is to say, the time in which she returns to her perigee or apogee, gives the *anomalistic month*: and, finally, the revolution with regard to the nodes is the *nodical* or *draconitic month*.

Of these different periods the most important to mankind is the synodic month. It is also that which, by reason of the striking manner in which it is marked out by the phases of the moon, would first offer itself to the attention of the observer; and when its period is accurately determined, the other months may be deduced from it without difficulty, when the relative motions of the sun and moon are known with sufficient precision. The eclipses furnish a simple means of determining the synodic revolution with a great degree of accuracy. A few rude observations suffice to show that the period of a lunation is very nearly 29½ days; and with this knowledge we are in a condition to compare two distant eclipses without running any risk of mistaking the number of revolutions that have taken place in the interval. The most ancient observation recorded by Ptolemy is an eclipse of the moon, which happened 720 years B.C., on the 19th of March, at 6 hours 48 minutes mean time at Paris, according to Lalande. In order to make use of this observation directly for the purpose of determining the synodic revolution, it is necessary to compare it with another of the same kind in which the moon occupied the

Theoretical Astronomy. same point of her ellipse, or the same position relatively to her apsides; for as it is the *true* place of the moon which is observed, and the *mean* motion which we are in quest of, the equation of the centre ought to be the same in both observations. Now, a similar observation is furnished by an eclipse which happened in 1717, on the 9th of September, at 6 hours 2 minutes, the moon's anomaly being very nearly the same as in the Babylonian observation. In the interval between the two observations the moon had therefore completed a whole number of revolutions, with regard to her mean as well as her true motion. The interval between the eclipses is 2437 years and 174 days minus 46 minutes, which expressed in days is 890287.9680555... days. In this interval it is found, from the approximate value of 29½ days, that 30148 synodic revolutions had happened; hence the mean length of

the synodic month is = $\frac{890287.968055}{30148} = 29$ days 12 hours 44 min. 2.8497 sec.

To deduce the other revolutions, let N = the number of days in a synodic month, n the number of synodic revolutions in the interval between the two observations, m the mean motion of the sun, and T the time of a tropical revolution. We shall then have the proportion $T : N :: 360^\circ : n \cdot 360^\circ + m$; whence

$$T = \frac{N \cdot 360^\circ}{n \cdot 360^\circ + m} = \frac{N}{n + \frac{m}{360^\circ}} = \frac{\left(\frac{N}{n}\right)}{1 + \frac{m}{n \cdot 360^\circ}} = \frac{N}{n} \left\{ 1 - \frac{m}{n \cdot 360^\circ} + \left(\frac{m}{n \cdot 360^\circ}\right)^2 - \&c. \right\}.$$

Let S = the time of a sidereal revolution. The value of S is immediately found from T ; for let p = the precession of the equinoxes in the time T , we shall have $S : T :: 360^\circ : 360^\circ - p$; whence

$$S = \frac{T \cdot 360^\circ}{360^\circ - p} = \frac{T}{1 - \frac{p}{360^\circ}} = T \left\{ 1 + \frac{p}{360^\circ} + \left(\frac{p}{360^\circ}\right)^2 + \&c. \right\}.$$

In like manner, if we represent by u the motion of the apside, and by v that of the node, in the time T , the times of the anomalistic and nodical revolutions will be respectively obtained by the substitution of u and $-v$ (the motion of the node being retrograde) in the last formula in place of p . Instead, however, of proceeding in this manner, it is better to assume as the basis of the calculation the mean motion of the moon in longitude, which is accurately known by the observations of 2000 years, and thence to deduce the time of the mean tropical revolution.

The mean motion of the moon in 100 Julian years, or 36525 days, is found to be 1336 circumferences + 307° 52' 43".5; or, by reducing the degrees, &c. to the fraction of a circumference, 1336.85521875 circumferences. The periodic month is therefore $\frac{35625}{1336.85521875}$ days. In order

to reduce the denominator of this fraction to a smaller number of digits, we may divide its terms by 3, multiply them by 32, then divide them by 900, and there will result $\frac{432.888...}{15.84421}$, the denominator of which contains only 7 digits in place of 12. On performing the division, we shall find the periodic month or tropical revolution = 27.321582388 days = 27 days 7 hours 43 min. 4.7183 sec.

Theoretical Astronomy. The mean motion of the moon in 36525 days
 is.....1336° 307' 52' 43".5
 that of the sun.....100 0 45 45

hence the relative motion is.....1236° 307' 6' 58".5
 = 445267.11625 degrees. The time of a synodic revolution is therefore $\frac{360 \times 36525}{445267.11625}$ days; or, multiplying nu-

merator and denominator by 800, = $\frac{10519200000}{356213693}$;

whence the synodic month is 29.5305885391 days = 29 days 12 hours 44 min. 2.849778 sec.

In order to obtain the sidereal revolution, we subtract the secular motion of the equinoctial points = 5010" = 1° 23' 30" from the moon's tropical revolution; the remainder, which gives the sidereal motion of the moon in 36525 days, is 1336° 306° 29' 13".5 = 481266.4870833 degrees. Hence the time of a sidereal revolution is

$\frac{360 \times 36525}{481266.4870833}$ days. On multiplying the terms of this

fraction by 2400, it is reduced to $\frac{31557600000}{1155039569}$, which gives

the sidereal month = 27 days 7 hours 43 min. 11.544375 sec.

In like manner, by subtracting the motion of the perigee in 100 years from the secular motion of the moon, we shall find the anomalistic revolution to be 27 days 13 hours 18 min. 34.9488 sec.; and by adding the retrograde secular motion of the node to the secular motion of the moon, the revolution in respect of the nodes is found to be performed in 27 days 5 hours 5 min. 35.60769 sec.

The following table exhibits the different kinds of lunar periods and motions:—

	Days.	Ho.	Min.	Sec.	Days.
Synodic revolution.....	29	12	44	2.84	= 29.5305887
Tropical.....	27	7	43	4.71	= 27.3215824

Tropical revolution of node }	..6728	4	17	43.18	= 6798.1789720
Sidereal.....	6793	6	59	15.34	= 6793.2911498
☾'s mean tropical daily motion.....	13°	10'	35".027		
☾'s mean sidereal daily motion.....	13°	10'	34".889		
☾'s daily motion in respect of node.....	13°	13'	45".534		

According to Ptolemy, the synodic month is 29 days

12 hours 44 min. $3\frac{1}{2}$ sec., which differs from the above only by half a second. The same great astronomer made the tropical month to consist of 27 days 7 hours 43 min. $7\frac{1}{2}$ sec. which exceeds the true time by $2\frac{1}{2}$ seconds; an error into which he was led by assigning too great a value to the mean motion of the sun.

The ancient astronomers paid great attention to these different revolutions, for the purpose of regulating their lunisolar calendar, and of avoiding the calculation of eclipses, which is attended with difficulties that to them must have proved almost insuperable. Their object was therefore to assign composite periods, after the revolution of which the eclipses would again return in the same order. Now, it is easy to see that a period which will bring back eclipses of the same magnitude and duration, on the same day of the year and at the same longitude, must be an exact multiple of the different lunar months. The return of the moon to the same distance from her node will give an eclipse of the same magnitude; if she returns at the same time to the same point of her orbit, the eclipse will also be of the same duration; and if, in addition to these circumstances, she has also returned to the same longitude, the eclipse will take place on the same day of the year. But the numbers in the above table being incommensurable, it is impossible to find any period, however long, that will embrace all these conditions; the ancients therefore formed periods of different lengths, according as they aimed at satisfying the different conditions with a greater or less degree of precision. For an account of some of the most remarkable of the ancient lunisolar periods, see CALENDAR.

On account of the acceleration of the mean motion of the moon, the ratios of the different species of months are constantly undergoing alterations, and therefore the different eyes, supposing them exact at the time of their formation, cannot continue so for an indefinite length of time. This circumstance is, however, little to be regretted; for, in the present state of astronomical science, they are not of any great use, inasmuch as we are in possession of surer methods of predicting eclipses, the calculation of which, from the ephemerides, is now a matter of comparative facility. They are, however, interesting in an historical point of view, and their formation was a principal object of the labours of the early astronomers. (On this subject see Lalande, *Astronomie*, tome ii. p. 185; Delambre, *Astronomie Théorique et Pratique*, tome ii. p. 319; Schubert, *Traité d'Astronomie Théorique*, tome ii.; Woodhouse's *Astronomy*, p. 665.)

Theoretical Astronomy. The mean motion of the moon in 36525 days is $12^{\circ} 31' 30''$ by 36525 that of the sun $12^{\circ} 31' 30''$ by 36525

hence the relative motion is $12^{\circ} 31' 30'' - 12^{\circ} 31' 30'' = 445267.14223$ degrees. The time of a synodic revolution is therefore $360 \times 36525 / 445267.14223$ days; or, multiplying nu-

merator and denominator by 800, $= \frac{10519200000}{356213693}$

whence the synodic month is 29.5305885391 days $= 29$ days 12 hours 44 min. 2.849778 sec.

In order to obtain the sidereal revolution, we subtract the secular motion of the equinoctial points $= 5010'' = 1^{\circ} 23' 30''$ from the moon's tropical revolution; the remainder, which gives the sidereal motion of the moon in 36525 days, is $1336^{\circ} 306' 29' 13''.5 = 481266.4870833$ degrees. Hence the time of a sidereal revolution is $360 \times 36525 / 481266.4870833$ days. On multiplying the terms of this

fraction by 2400, it is reduced to $\frac{31557600000}{115639569}$, which gives the sidereal month $= 27$ days 7 hours 43 min. 11.544375 sec.

In like manner, by subtracting the motion of the perigee in 100 years from the secular motion of the moon, we shall find the anomalistic revolution to be 27 days 13 hours 18 min. 34.9488 sec.; and by adding the retrograde secular motion of the node to the secular motion of the moon, the revolution in respect of the node is found to be performed in 27 days 3 hours 3 min. 57.6114 sec.

The following table exhibits the different kinds of lunar periods and motions:—

	Days.	Hrs.	Mins.	Secs.	Days.
Synodic revolution.....	29	12	44	2.849778	29.5305885391
Tropical.....	27	7	43	11.544375	27.309138223
Sidereal.....	27	7	43	11.544375	27.309138223
